Abstract

Polycyclic Aromatic Hydrocarbons (PAHs) are ubiquitous and persistent soil pollutants. Their fate and the influence of the plant rhizosphere on their dynamics has been extensively studied, but studies mainly focused on their dissipation rate. We conducted a plant-soil mesocosm experiment to study the fate and distribution of PAHs or derived compounds in the extractable fraction, the residual soil, the shoot biomass and the root biomass. The experiment was conducted for 21 days using ryegrass and a forest soil spiked with $^{13}$C-labeled phenanthrene (PHE), using combined IRMS and NanoSIMS for analyses. Almost 90% of the initial extractable PHE content was dissipated within 3 weeks, but no rhizospheric effect was highlighted on PHE dissipation. More than 40% of $^{13}$C-PHE was still in the soil at the end of the experiment, but not as PHE or PAH-derived compounds. Therefore it was under the form of new compounds (metabolites) and/or had been incorporated into the microbial biomass.
About 0.36% of the initial $^{13}$C-PHE was recovered in the root and shoot tissues, representing similar $^{13}$C enrichment ($E^{13}$C) as in the soil ($E^{13}$C ≈ 0.04 at.%). Using NanoSIMS, $^{13}$C was also localized at the microscale in the roots and their close environment. Global $^{13}$C enrichment confirmed the results obtained by IRMS. Some hotspots of $^{13}$C enrichment were found, with a high $^{32}$S/$^{12}$C$^{14}$N ratio. Comparing the ratios, sizes and shapes of these hotspots suggested that they could be bacteria.

**Keywords:** Polycyclic Aromatic Hydrocarbons; $^{13}$C-Phenanthrene; soil; rhizosphere; IRMS; NanoSIMS

**Highlights:**

- A mesocosm experiment with $^{13}$C-PHE-spiked soil was analyzed by IRMS and NanoSIMS
- 40% of $^{13}$C-PHE was still in the soil after 21 days but not as the parent compound
- Bacterium-like $^{13}$C-enriched hotspots were revealed by NanoSIMS close to the roots

1. **Introduction**

Polycyclic Aromatic Hydrocarbons (PAHs) are ubiquitous and persistent organic compounds found in the soils of large brownfield areas in many former industrial regions. They are composed of two or more benzene rings and result from the incomplete combustion by pyrolysis of organic materials from natural or anthropogenic sources (Edwards, 1983). They are persistent in soils due to their low water solubility and high adsorption on soil constituents (Wilson and Jones, 1993). They are harmful to human and environmental health, and 16 of them are listed as priority pollutants by the USEPA (Hartmann, 1996).
Many studies have addressed the fate and dynamics of PAHs in soils, where they can undergo numerous processes such as plant uptake, stabilization by sorption on organic and mineral phases, or transformation and degradation until total mineralization. Sorption and degradation are key processes in the fate of PAHs in the environment (Magee et al., 1991). The persistence of organic pollutants in soils has been attributed to sequestration mechanisms including intra-organic matter and intra-particle diffusion of the parent compound and transformation products (Doick et al., 2005). Plants seem to have a limited direct impact on PAH dynamics in polluted soils (Fang et al., 2001; Günther et al., 1996; Rezek et al., 2008). Gao and Zhu (2004) showed that uptake of phenanthrene and pyrene by plants accounted for less than 0.01 and 0.23% of enhanced loss in vegetated versus non-vegetated soils. The low water solubility of PAHs could prevent significant uptake by plant tissues (Binet et al., 2000; Kipopoulou et al., 1999) and root-to-shoot translocation (Burken and Schnoor, 1998). However, the indirect role of plants in PAH dynamics through their root systems is largely documented (Rezek et al., 2008; Miya and Firestone, 2000; Liste and Alexander, 2000). The plant rhizosphere is a favorable environment for high microbial diversity and activity, which permit higher PAH dissipation in soils (Corgié et al., 2003; Anderson et al., 1993; Schwab, 1994; Reilley et al. 1996). The main mechanisms involved in PAH dissipation in the soil and the rhizosphere are biodegradation and biotransformation by an active microflora (Binet et al., 2000; Wilson and Jones 1993; Cerniglia, 1997). The soil heterotrophic microflora may use organic pollutants as a source of carbon (C) and energy to grow, or for co-metabolism (Hwang and Cutright, 2002). The C derived from PAHs (C-PAH) could be (i) incorporated into the microbial biomass (Kästner et al., 1999), and/or (ii) transformed into other organic compounds and thus form part of non-extractable PAHs (Richnow et al., 1998 and 1999). The newly formed organic products could be more reactive than the parent compounds and therefore bind with soil components more easily, but could also be more toxic (Sabaté et al., 2006). Cébron et al.
(2011) showed that 38% of the $^{13}$C from labeled PAH added into soil mesocosms was not extractable after 12 days. C-PAH was still present but probably not under the form of parent PAHs or extractable compounds. Some of these newly formed organic compounds may be more soluble and more mobile than parent PAHs (Sabaté et al., 2006). However, most of the studies led so far only considered the dissipation of PAHs in the soil and in the plant rhizosphere. Some studies focused on the residual and newly formed organic compounds, especially on the distribution and the dynamics of C-PAH in the soil (Doick et al., 2005; Eschenbach et al., 1998; Kästner et al., 1999; Macleod and Semple, 2003; Northcott and Jones, 2001; Richnow et al., 1998), but no in soil-plant-microflora compartments.

An effective and relevant way to trace carbon compounds in soil-plant ecosystems is to use $^{13}$C isotopic labeling. For example, Richnow et al. (2000, 1998) used [1-$^{13}$C]-PAH to trace the transformation of phenanthrene in a soil reactor. But it appears more relevant to monitor C-PAH using a molecule labeled on all its carbon atoms (Cébron et al., 2011). Another complementary method to trace a labeled organic compound in soils, plants or bacteria is to map isotopic distribution at a microscale through NanoSIMS analyses (high-resolution imaging Secondary Ion Mass Spectrometry) (Hoppe et al., 2013). NanoSIMS analyses can map all the elements (isotopes) of the periodic table with an ultimate lateral resolution (probe size) in the 50 to 150 nm range, high sensitivity (a few ppm), and high mass resolution (Herrmann et al., 2007; Moore et al., 2012; Remusat et al., 2012; Vidal et al., 2016).

The objective of our study was to investigate the fate of C-PAH in planted and non-planted soil by assessing (i) the distribution of C-PAH in the extractable fraction, the residual soil, the shoot biomass and the root biomass, and (ii) the localization of C-PAH in different compartments of the soil-plant system. We conducted a mesocosm trial using ryegrass, $^{13}$C-phenanthrene ($^{13}$C-labeled on all its carbon atoms) soil spiking, and coupling isotopic analyses with NanoSIMS analyses.
2. Materials & methods

2.1. Soil-plant mesocosms

Planted and non-planted mesocosms were set up, with soil spiked with either unlabeled $^{12}$C-PHE (control) or labeled $^{13}$C-PHE. The soil was a Calcisol, sampled at 5-35 cm depth in a temperate beech forest close to a former coking plant (49°14.163’N, 6°0.116’E, Homecourt, Lorraine region, France). The soil horizon had a pH$_{\text{water}}$ of 7.3; it contained 48% clay, 44% silt, 7% sand, had organic carbon and total nitrogen contents of 23.0 and 1.62 g kg$^{-1}$ respectively, and a low PAH content (13.4 mg kg$^{-1}$). The soil sample was air-dried, ground and sieved to 2 mm, and then spiked with 300 mg PHE kg$^{-1}$ of soil. Spiking modalities were as follows: one with unlabeled PHE ($^{12}$C-PHE, Sigma Aldrich >97%) and two with known $^{13}$C-PHE/$^{12}$C-PHE mixtures ($^{13}$C-PHE, Sigma-Aldrich Isotec Stables Isotopes, Miamisburg, Ohio, USA). The $^{13}$C-PHE/$^{12}$C-PHE ratio was 1:8 for organic carbon analyses and 1:1 for NanoSIMS analyses. A PHE-hexane solution was added to 1:10 of the total soil mass for spiking. Hexane was evaporated under a fumehood, and then the spiked soil was homogenized with the remaining 9:10 of soil mass.

The planted and non-planted mesocosms were conducted in 50-mL glass jars with 40 g of PHE-spiked soil. They were inoculated with 10 mL of soil suspension from a PAH-contaminated soil (200 g L$^{-1}$ in 0.85% NaCl) to ensure that a PAH-degrading microflora was present. Five ryegrass ($\text{Lolium perenne}$) seeds were added in each planted mesocosm. The experiment was conducted in a growth chamber under controlled conditions (22°C/18°C with 16h/8h day/night, 250 µmol photons m$^{-2}$ s$^{-1}$, 80% relative humidity) for 21 days. Four replicates were prepared for each planted and non-planted modality and each sampling time (0, 7, 14 and 21 days), and for each $^{12}$C-PHE- and $^{13}$C-PHE/$^{12}$C-PHE- (1:8 ratio) spiked soil, except for 1:1 $^{13}$C-PHE/$^{12}$C-PHE-spiked soil (one replicate, and sampling after 7 and 14 days for NanoSIMS microprobe analyses). At each sampling time, ryegrass shoots and roots were removed from
the soil and separated. The roots were washed with distilled water and dried with filter paper.

The fresh plant material and soil were oven-dried at 35 °C and then ground, and the soil was sieved to 200 µm prior to analyses. The roots were prepared directly after sampling for elemental mapping analyses.

2.2. Organic and isotopic analyses

PHE was extracted from 2 g of dry soil using dichloromethane (DCM) and a high-pressure and high-temperature DIONEX® 200 ASE (Accelerated Solvent Extractor) automated extractor. Residual soil (after PAH extraction) was kept for organic analyses. DCM was evaporated from the PAH extracts under N₂ flow and replaced by acetonitrile for PAH analysis. PAH extracts were analyzed using a reverse-phase chromatography UHPLC Ultimate 3000 RSLC system (Dionex) equipped with a Diode Array Detector and a Zorbax Eclipse PAH RRHD column (100 mm x 2.1 mm, 1.8 µm – Agilent). The mobile phase was a mixture of water/acetonitrile in gradient mode, with a flow rate of 0.420 mL min⁻¹. The wavelength used for detection was 254 nm.

Isotopic and elemental analyses were performed on bulk and residual soil (before and after PAH extraction, respectively), and on ryegrass shoot and root biomass using EA-GC/IRMS (Elementary analyzer – Isotope Ratio Mass Spectrometry 100, IsoPrime, Manchester. EA: IsotopeCube, Elementar, Hanau). Approximately 1.0 mg of the powdered material of each sample was weighed and placed in 6x4 mm tin capsules (Elemental Microanalysis Limited, Devon, UK). Analyses were carried out at the Technical Platform of Functional Ecology (OC 081) at the INRA Forest Ecology and Eco-Physiology Unit. Isotopic measurements were reported in the delta notation (δ expressed in ‰) as:
$\delta^{13}C\ (\%) = (\frac{R_{sample}}{R_{Ref}} - 1) \times 1000 \quad \text{Eq. 1}$

Where $R_{sample} = \frac{^{13}C_{sample}}{^{12}C_{sample}}$ for labeled and control samples, and $R_{Ref}$ refers to the Vienna Pee Dee Belemnite (VPDB) standard, with $R_{Ref} = \frac{^{13}C_{PDB}}{^{12}C_{PDB}} = 0.0112375$.

Enrichment in $^{13}C$ ($E^{13}C$), expressed as excess % of atoms (at.%), was calculated relatively to the unlabeled control in the soil and in the plant, as follows:

$E^{13}C\ (\text{at.}%) = \frac{^{13}C_{labeled} - ^{13}C_{control}}{^{13}C_{control}} \times 100 \quad \text{Eq. 2}$

Where $^{13}C_{labeled}$ (at.%) = $\frac{R_{labeled}(R_{labeled}+1)}{R_{control}} \times 100$, $^{13}C_{control}$ (at.%) = $\frac{R_{control}(R_{control}+1)}{R_{labeled}} \times 100$.

$E^{13}C$ was calculated for bulk soil, residual soil, and ryegrass shoot biomass and root biomass.

Soil and plant $^{13}C$ concentrations ($^{13}C_{conc}$) were also calculated (expressed as $\mu g\ C\ g^{-1}$ of soil and $\mu g\ C\ g^{-1}$ of plant, respectively):

$^{13}C_{conc} (\mu g\ C\ g^{-1}) = \left( \frac{^{13}C_{conc}}{^{12}C_{conc}} \right) \times C_x \quad \text{Eq. 3}$

Where $C_x$ refers to the C content, expressed in $\mu g\ C\ g^{-1}$ of soil or plant. $^{13}C$ distribution (%) in the mesocosms was deduced from the $^{13}C$ concentrations and by considering that the percentage of $^{13}C$ initially added in the soil after PHE-spiking was 100% (T0). $^{13}C$ distribution (%) was calculated for the PAH extracts, the residual soil and the plants. The remaining $^{13}C$ was considered as $^{13}C$ loss.

2.3. Elemental mapping analyses in the roots

The fresh ryegrass roots harvested after 7 and 14 days were rapidly cut into 0.5-cm pieces and placed on adhesive film. The fine roots were cryofixed using a LEICA EM CPC Universal Cryoworkstation. They were frozen at atmospheric pressure ($10^5\ °C\ s^{-1}$), and slammed on copper mirrors (Printz et al., 2016). Then the cryofixed samples were lyophilized (LEICA EM CFD) without using any solvent ($1^\circ C\ h^{-1}$ for 8 days down to $-20\ °C$ at $1.10^{-4}\ Pa$) (Printz et al., 2016). The root samples were finally embedded in Epoxy resin and coated with gold prior to analyses by nano Secondary Ion Mass Spectrometry.
Elemental mapping was performed using a Cameca NanoSIMS 50 ion probe (Gennevilliers, France) in the raster-imaging mode. The probe detects the secondary ions generated from each pulverized sample surface by an energetic incident ion beam (Hoppe et al., 2013). Ion images were obtained using a beam of Cs⁺ primary ions with an energy impact of 16 keV and a beam current of 0.8 pA on the sample. The images were recorded in 256x256 pixels; under these conditions, a lateral resolution of 80-100 nm was expected. Negative secondary ion signals for \(^{12}\text{C},^{13}\text{C},^{12}\text{C}^{14}\text{N},^{32}\text{S}\) ions and \(^{12}\text{C}^{14}\text{N},^{56}\text{Fe}^{16}\text{O}\) clusters (Behrens et al., 2008) were collected simultaneously using the multicollection system. Images were acquired with a counting time of 30 ms/pixel. Mass resolution (M/ΔM) was above 4500 (e.g. 2916 was required to resolve mass interference between \(^{13}\text{C}\) and \(^{12}\text{C}^{1}\text{H}\)), and mass calibration was achieved using standard iron oxide references. The isotope ratio of the two \(^{12}\text{C}\) and \(^{13}\text{C}\) carbon isotopes allowed us to localize and quantify the \(^{13}\text{C}\)-labeled PHE. The quantitative data acquired by NanoSIMS were calculated with Winimage software that directly processes image data (CAMECA file format) and measures the δ\(^{13}\text{C}/\text{C}^{12}\text{C}\) isotopic deviation according to the δ\(^{13}\text{C}/\text{C}^{12}\text{C}\) formula (Eq. 1) for each pixel. The deviation of the \(^{13}\text{C}/\text{C}^{12}\text{C}\) ratio was calculated based on a fixed R\(_{\text{ref}}\) value (commonly 1.107%, the natural isotope ratio for \(^{12}\text{C}\)). The isotopic ratio of \(^{13}\text{C}\) determined by NanoSIMS was not compare to IRMS values because of the presence of the epoxy resin which prevent a specific \(^{13}\text{C}\) signal of organic matter (Vidal et al., 2016). The scale of all the images of isotopic map deviation was kept constant (0 to 300) to allow for a quick comparison of intensity levels.

Carbon-to-nitrogen (\(^{12}\text{C}/^{13}\text{C}^{14}\text{N}\)) and sulfur-to-nitrogen (\(^{32}\text{S}/^{12}\text{C}^{14}\text{N}\)) ratio data were extracted from regions of interest (ROIs) by using the freeware package Image J. Each ROI was drawn at least twice for each group in order to obtain a mean ratio for any given area. Linescan (=segments of variable length drawn on the ion image) data were also extracted using OpenMIMS plugging with ImageJ software. Preparation and SIMS analyses were carried out
with a Cameca NanoSIMS 50 at the Luxembourg Institute of Science and Technology (LIST) in Esch-sur-Alzette, Luxembourg.

2.4. Statistical analyses

Statistical analyses were performed using R software (version 3.1.3, 2015). All tests were used with a 95% significant level. Parametric conditions were checked with Shapiro-Wilk’s test for normality and with Bartlett’s test for homogeneity of variance. When normality conditions were not met, a non-parametric statistical test was used for multiple comparisons of means. Two-way analysis of variance (ANOVA 2) followed by Tukey’s post hoc test was used for the comparison of PHE and $^{13}$C concentrations between sampling times and between treatments. For NanoSIMS analysis, the relative abundance levels of $^{13}$C from ROI were compared with a non-parametric analysis of variance (Kruskal-Wallis test).

3. Results

3.1. Phenanthrene concentrations in planted and non-planted mesocosms

The extractable PHE concentration immediately after soil spiking (T0) was $171.6 \pm 0.7$ mg kg$^{-1}$ (Figure 1). After 7 days, PHE concentrations were $128.1 \pm 9.7$ and $137.6 \pm 10.8$ mg kg$^{-1}$ in the planted and non-planted mesocosms, respectively, indicating 20-25% PHE dissipation. The main decrease in PHE concentration was noted after 14 days, with $49.8 \pm 15.6$ and $40.2 \pm 15.9$ mg kg$^{-1}$ of PHE in the planted and non-planted mesocosms, respectively, i.e. approximately 70% of PHE loss. Finally, after 21 days there remained less than 20 mg kg$^{-1}$ of PHE in each mesocosm. The PHE concentration decreased significantly over time: 90% of the
added PHE was dissipated after 21 days. No significant difference in PHE concentrations was noted over time between the planted and non-planted mesocosms.

3.2. \(^{13}\)C-enrichment and distribution in the planted and non-planted mesocosms

\(^{13}\)C-enrichment (E\(^{13}\)C) values are summarized in Table 1 and Figure 2a. No significant difference in E\(^{13}\)C was noted between the planted and non-planted mesocosms. E\(^{13}\)C of the bulk soil decreased from 0.097 at.% at T0 down to 0.047 at.% after 21 days, while E\(^{13}\)C of the residual soil increased from 0.005 at.% to 0.044 at.% over the same time period. At the end of the trial, there was no significant difference in \(^{13}\)C concentration between the bulk and residual soils, indicating that \(^{13}\)C was mainly present in the residual soil under a non-extractable form (Table 1). E\(^{13}\)C in plant tissues was studied after 7 days. It reached 0.015 at.% and 0.017 at.% in the roots and shoots, respectively. From 14 days, no significant difference was noted between root and shoot E\(^{13}\)C due to the high heterogeneity of values. After 21 days, E\(^{13}\)C in residual soil as well as in ryegrass shoots and roots was around 0.04 at.%.

\(^{13}\)C distribution was measured over time for the different compartments of the mesocosms: residual soil, PAH extract, plant, and C loss (Figure 2b). At T0, 94% of the total \(^{13}\)C content was recovered in the PAH extract, and 6% in the residual soil. The \(^{13}\)C content of the PAH extract decreased over time down to 3-11% of the total \(^{13}\)C content, while it increased significantly in residual soil and reached 45-48% of the total \(^{13}\)C content after 21 days. The ryegrass \(^{13}\)C content represented less than 1% of the total \(^{13}\)C content, mainly due to the very low dry mass as compared to the total mass of soil (a few mg versus 40 g). The \(^{13}\)C loss from mesocosms accounted for 19% after 7 days and up to 43% after 14 days.
3.3. Mapping of $^{13}$C enrichment in ryegrass roots

NanoSIMS analyses were carried out on unlabeled and labeled roots after 7 and 14 days. The mean percentages of $^{13}$C atoms in the roots were 1.09 in unlabeled (control) roots, 1.11 in $^{13}$C-labeled roots after 7 days, and 1.15 in $^{13}$C-labeled roots after 14 days. A significant $^{13}$C-enrichment was noted in labeled roots after 14 days relatively to the control.

A mapping of $^{13}$C associated with $^{12}$C,$^{13}$C$^{14}$N, $^{32}$S,$^{56}$Fe$^{16}$O ion species was performed on root cross sections after 14 days (Figure 3). The roots were clearly identified in association with high $^{12}$C, $^{12}$C$^{14}$N and $^{32}$S signals. The resin was clearly visible with high $^{12}$C levels but no $^{12}$C$^{14}$N or $^{32}$S intensity, and was easily differentiated from the root tissue. Mineral particles such as iron oxides, assimilated to soil particles, were highlighted by the $^{56}$Fe$^{16}$O$^{-}$ signal and they were only observed surrounding the root. The composite image resulting from the overlay of $^{12}$C, $^{12}$C$^{14}$N and $^{13}$C elements emphasized $^{13}$C enrichment localization. There was no visual evidence of global $^{13}$C enrichment in the roots, but rather locally distributed hotspots. Three zones were identified close to the root epidermis (Figure 4), but none close to the soil particles. These hotspots were mainly oval-shaped, and 1 to 2 $\mu$m in diameter.

An area of interest, pinpointed by the white square in Figure 3, was enlarged and presented in Figure 4.a) Hotspots (red), root (green and blue association), soil (white) and resin (green) were well identified. The black zone between the resin and the root could be holes that formed during sample preparation. The hotspots were adherent to the root epidermal cells but not to the soil particles. A linescan was drawn through root and hotspots (Figure 4.b) to study $^{12}$C, $^{13}$C, $^{12}$C$^{14}$N and $^{32}$S distribution. It showed that a higher $^{13}$C signal as compared to $^{12}$C was correlated with a higher $^{32}$S signal as compared to $^{12}$C$^{14}$N. This higher $^{32}$S signal as compared to $^{12}$C$^{14}$N was not observed in the root but only in the hotspot, so that the hotspots appeared to be made of something else than root tissue. $^{12}$C/$^{13}$C$^{14}$N, $^{32}$S/$^{12}$C$^{14}$N and $^{56}$Fe$^{16}$O/$^{12}$C ratios were also calculated for ROI selection in the hotspots, root tissue, soil particles and resin (Table 2).
Hotspots were easily discriminated from roots because they displayed significantly higher $^{12}$C/$^{13}$C$^{14}$N and $^{32}$S/$^{12}$C$^{14}$N ratios. They were not considered as soil particles because they had a low $^{56}$Fe$^{16}$O/$^{12}$C ratio, or as resin because they contained less C than resin ($^{12}$C/$^{13}$C$^{14}$N ratios equivalent to 12.88 for resin and 1.02 for hotspots).

### 4. Discussion

#### 4.1. Effect of the rhizosphere on phenanthrene degradation

The extractable PHE concentration decreased by 40% after spiking and by up to 90% after 21 days in the planted and non-planted systems (Figure 1). This rapid dissipation of PHE and its high rate are in part explained by experimental conditions, including the high bioavailability of the freshly spiked pollutant and soil inoculation with adapted microflora. Smith et al. (2011) showed that using a soil freshly spiked with pure PAH led to a greater loss than using historically contaminated soils. Inoculation of a microflora extracted from PAH-contaminated soil had a priming effect in the first days following contamination and increased PHE degradation (Joner et al., 2004, 2002). Low-molecular-weight PAHs such as PHE (3 rings) can be used as primary substrates and be easily broken down in the soil by adapted microflora commonly found in polluted soils (Cerniglia, 1997). This rapid PHE degradation could mask a potential rhizospheric effect, even in a forest soil. No significant difference was noted in $^{13}$C-dynamics between the planted and non-planted systems (Figure 2). Therefore there is no evidence of an impact of the rhizosphere on PAH degradation in this type of plant-soil mesocosm.

#### 4.2. Dynamics of phenanthrene carbon in the plant-soil mesocosms

The dynamics of PHE degradation was studied by monitoring the increase in C loss and C incorporation in the soil (Figure 2.a). The loss of $^{13}$C during the first 14 days
represented half of the spiked $^{13}$C (Figure 2.b). We hypothesized that a major part of the PHE loss was mineralized as CO$_2$. There was no significant difference in PHE degradation between 14 and 21 days, which means that PHE degradation occurred during the first days of contamination.

After 14 days, almost 40% of PHE carbon had been incorporated in the soil. This result is in accordance with the 38% of $^{13}$C remaining in the soil after 12 days in comparable soil mesocosms used to identify PAH-degrading bacteria (Cébron et al., 2011). No PHE metabolite, like those identified by Käcker et al. (2002) and Richnow et al. (2000) for example, was detected by GC-MS analysis of PAH extracts. The remaining $^{13}$C incorporated in the soil must then have been present under the form of other organic compounds that were not extracted by dichloromethane. Kästner et al. (1999) conducted a long-term experiment on the transformation of $^{13}$C-labeled PAHs in soil bioreactors; they highlighted that the non-extractable residue had a relatively high stability over time. These organic compounds, newly formed from PAHs, become soil-bound residues (Binet et al., 2000) and/or a C source for microorganisms (Richnow et al., 1998; 2000). For Richnow et al. (1999), the formation of these compounds most probably depends on an intense microbial activity. Soil microorganisms may use organic pollutants like PAHs as a C source and transform them into biomass through anabolic processes. Part of these newly formed compounds can also be incorporated into organo-mineral complexes and be protected against degradation depending on the nature of mineral phases (de Junet et al., 2013). This could explain why these organic compounds remain non-available in the soil (Macleod and Semple, 2003; Pignatello and Xing, 1996) and have a relative high stability (Richnow et al., 1999).

Less than 1% of total PHE carbon was taken up by ryegrass roots and shoots. No significant difference was noted between the two plant parts after 14 and 21 days. Plant $^{13}$C enrichment was similar to soil $^{13}$C enrichment, namely about 0.04 at.% (Figure 2a), and
the difference expressed in total amounts was only due to the difference in mass between
the soil and the plants. However, according to NanoSIMS analyses (Figure 4), there was
no evidence of direct PHE uptake by plant roots. A small part of PHE may have been
sorbed onto the root epidermis, more precisely near the suberized exodermis and
endodermis (Dupuy et al., 2016). Previous studies show preferential PAH incorporation in
shoots through atmospheric deposition, and low direct incorporation by roots (Binet et al.,
2000a; Desalme et al., 2011; Schwab and Banks, 1994). If $^{13}$C was not taken up by the
roots under the form of PHE, it may have been taken up under the form of newly formed
organic compounds or $^{13}$C-CO$_2$. It could be absorbed or adsorbed from ambient air by the
shoots after PHE volatilization (Gao and Zhu, 2004) or through stomata under the form of
$^{13}$C-CO$_2$ during the photosynthetic process. $^{13}$C enrichment was also noted in roots by SIMS,
confirming the excess $^{13}$C recovered in the roots (Figure 2.a).

4.3. Determination of $^{13}$C hotspots and localization of $^{13}$C in ryegrass roots

There was no correlation between the $^{56}$Fe$^{16}$O and $^{13}$C signals close to the roots after 14
days, therefore SIMS analyses did not evidence any contribution of organic matter-mineral
associations to the $^{13}$C-PAH dynamics. However two types of enrichment were highlighted
in the plant rhizosphere: a global $^{13}$C enrichment and $^{13}$C hotspots. Hotspots were composed
of $^{12}$C, $^{12}$C$^{14}$N and $^{32}$S ions species. Sulfur and nitrogen contents suggest the presence of
proteins (Eybe et al., 2008) that could originate from the plants or from microorganisms.
Hotspots were discriminated from root tissues based on their high $^{32}$S content as compared to
the roots (Figure 4 and Table 2). The $^{32}$S/$^{12}$C$^{14}$N ratio of the hotspots (0.11) was around five
times higher than the $^{32}$S/$^{12}$C$^{14}$N ratio of the ryegrass roots (0.02). This last value is in
accordance with the $^{32}$S/$^{12}$C$^{14}$N ratio of 0.027 found by Dijkshoorn and Van Wijk (1967) in
ryegrass shoots. The oval shape of the hotspots and their size (1 to 2 $\mu$m in diameter) are in
accordance with the shape and size of bacteria. Moreover, measurements were performed on isolated bacteria (unpublished data) and showed similar ratios (0.1 for $^{32}\text{S}/^{12}\text{C}^{14}\text{N}$). There was evidence of global $^{13}\text{C}$ enrichment during plant growth, but no PAH uptake by the roots was visualized by NanoSIMS analyses (Figure 4). The main $^{13}\text{C}$-PAH uptake could be attributed to the bacteria present in the rhizospheric environment.

5. Conclusion

A mesocosm experiment was conducted using $^{13}\text{C}$-phenanthrene to monitor the dynamics of PHE and derived compounds in the soil and in ryegrass. After 21 days, almost 90% of spiked PHE had been degraded. PHE was mainly mineralized under gas phase (up to 53%, corresponding to the $^{13}\text{C}$ loss). But after 14 days, more than 40% of PHE carbon had been transformed into newly formed organic compounds (metabolites) or incorporated into the microbial biomass. No rhizospheric effect on PAH dynamics was noted due to the rapid dissipation of PHE. Less than 1% of PHE carbon was also found in the root and shoot tissues of ryegrass. The plant $^{13}\text{C}$ was similar to the soil $^{13}\text{C}$ (~ 0.04 at.%), suggesting a homogeneous $^{13}\text{C}$-PAH distribution in the plant-soil mesocosm.

Global root $^{13}\text{C}$-PAH enrichment was also determined in the ryegrass rhizosphere at a finer scale using NanoSIMS, based on $^{13}\text{C}/^{12}\text{C}$ ratio measurements on images obtained for control ($^{12}\text{C}$) and labeled samples after 7 and 14 days. There was no evidence of $^{13}\text{C}$-PAH association to iron oxides in the close root environment. However, hotspots of $^{13}\text{C}$ enrichment close to the roots probably indicated the presence of bacteria, as suggested by their size, shape and element composition. A part of PAH carbon was sorbed on the roots, but it was mainly incorporated into the bacteria mentioned above. These bacteria probably degraded PHE and incorporated PHE-derived $^{13}\text{C}$ into their biomass.
The use of labeled contaminants and the coupling of IRMS and NanoSIMS is a relevant and powerful tool for determining the dynamics of these contaminants. The dynamics of $^{13}\text{C}$ from labeled PAH was highlighted by $^{13}\text{C}$-partitionning at a global level, but the transformation of PAH $^{13}\text{C}$ at a molecular level remains to be investigated. Complementary techniques such as $^{13}\text{C}$-NMR and pyGCMS could be used to further characterize the $^{13}\text{C}$-PAH metabolites.

**Figure 1.** Extractable concentrations of phenanthrene (PHE, mg kg\(^{-1}\) of soil) in planted and non-planted mesocosms at different time-points over a 21-day period. Means ± SD, n = 4. Different letters indicate significant differences (p<0.05) between the sampling times.
Figure 2. $^{13}$C dynamics after $^{13}$C-PHE spiking in non-planted (left) and planted (right) mesocosms at different time-points over a 21-day period. (a) $^{13}$C enrichment ($E^{13}$C, at.%) in the plant and soil compartments. Means ± SD, n = 4. $^{13}$C enrichment was calculated from $\delta^{13}$C data obtained by EA-IRMS. (b) $^{13}$C distribution in the mesocosm compartments (PAH extract, residual soil, plant, and C loss). Results are expressed as percentages of the $^{13}$C-PHE concentrations initially added in the soil. The plant compartment gathers root and shoot data. PAH extract concentrations were calculated as the difference between bulk and residual soil concentrations.
Figure 3. NanoSIMS elemental maps of $^{12}$C, $^{13}$C, $^{12}$C$^{14}$N, $^{32}$S and $^{56}$Fe$^{16}$O from labeled ryegrass roots after 14 days. The 90*90-$\mu$m$^2$ images are cross views of whole roots with adherent soil particles. A composite image (bottom right) was obtained by overlaying the $^{12}$C-, $^{12}$C$^{14}$N and $^{13}$C images. Three areas of interest (bordered in white) with higher $^{13}$C content were identified. NanoSIMS data were analyzed using Winimage software.
