Abstract:

Filter market demand pushes to the development of new piezoelectric materials to address modern telecommunication challenges. Composite wafers combining an epitaxial piezoelectric layer and a said high velocity and acoustic quality substrate is a promising way to answer that demand. However, the fabrication of high-quality LiNbO₃ films with reproducible physical properties is complicated by the difficulty to control volatile Li₂O incorporation into the film and to measure its composition. So far, large-scale production of films with physical properties suitable for the targeted applications is not available. In this paper, lithium niobate films with controlled nonstoichiometry were deposited by means of pulsed injection metalorganic vapor phase deposition. We have demonstrated a high acoustical performance for surface acoustic wave (SAW) devices operating in the frequency range from 3.7 GHz up to 5.3 GHz and based on grown epitaxial Z-axis oriented LiNbO₃ films on sapphire. An electromechanical coupling of 8 % for the Rayleigh wave at 5.3 GHz was demonstrated experimentally.

Keywords: SAW, LiNbO₃ films, high frequency, CVD, waveguide

Radio-frequency (RF) filters are widely used in the field of telecommunications (smart phones, wi-fi, Bluetooth, automotive navigation, etc.). The next generation of radiofrequency (RF) telecom applications urgently requires filters operating at frequencies above 3 GHz, particularly operating in the C-Band (4-6 GHz). The conventional RF surface acoustic wave (SAW) filters are presently mainly fabricated on LiNbO₃ (LN) and LiTaO₃ (LT) single crystal substrates. The frequency of SAW devices is defined at first order by the period of interdigitated transducers (IDTs) and by the SAW phase velocity. The minimum period of IDTs, used in SAW industry mainstream, is 700 nm and the phase velocity of the available single crystal materials (4200 - 4600 m·s⁻¹ and 3900 - 4200 m·s⁻¹ for leaky shear waves in LN and LT, respectively), compatible with large - scale production, represent strong limits in that matter. So far, the frequency of RF SAW filters, produced at industrial scale, is limited to about 3.2 GHz. New low-loss materials with sufficiently high electro-mechanical coupling (K_s^2) and high acoustic velocities

are needed to achieve SAW filters at above-mentioned frequencies. A promising approach to satisfy this demand is to use guided acoustic waves in the piezoelectric layers.

Guided acoustic waves can be generated in piezoelectric layers on substrates presenting higher phase velocity than that of the piezoelectric film.¹ As guided waves are dispersive by essence, the piezoelectric film thickness has to be adjusted in order to achieve specific frequencies, to optimize the electromechanical coupling, K_s^2 , and to limit higher order mode contributions.² The highest velocities can be attained at low h/λ ratio (where h is a piezoelectric film thickness and λ is the wavelength imposed by IDTs) to the price of maximum dispersion effects. This guiding phenomenon, enabling a significant increase of the propagation velocity, was broadly studied in the literature. In the case of LN and LT sub-micron films, diamond and sapphire substrates were mainly considered for this purpose.³⁻⁶ Sapphire substrates are of particular interest due to their availability under the form of wafers with diameters in the range 100 – 200 mm, and their very low acoustical absorption (very low equivalent viscous-acoustic losses).⁷ It was shown by means of simulations that acceleration of the acoustic waves could be achieved for different orientations of LN and LT films on different cuts of sapphire substrates.^{3,5,8} The increased propagation velocities were demonstrated experimentally on (YX)LN/R-sapphire,^{3,8} (YX)-LT/R-sapphire,⁸ and (ZX)-LN/C-sapphire³ heterostructures (where C stands for (ZX) orientation and R – (33°YX) orientation according IEEE Std-176 convention),⁹ as well. The phase velocity of Leaky wave in (ZX)-LN/C-Sapphire with $h/\lambda = 0.035$ was $6480 \text{ m}\cdot\text{s}^{-1}$.⁸ However, the insertion losses of SAW devices based on LN/LT films, reported in literature, were (8 - 50 dB) incompatible with the industrial requirements ($< 5 \text{ dB}$).¹⁰ It is worth noting that the studied devices operated at relatively low frequencies (several 100s of MHz) and that low losses are more difficult to achieve at frequencies above 2 GHz as the wave propagation is more affected by the film roughness and the defects presents in the film. Moreover, the measured electromechanical coupling, K_s^2 , of SAW devices based on LN/LT films was very low and it was not higher than 1 % although much higher values are expected theoretically.¹⁰ This indicates that further ameliorations of LN film quality and the development of high frequency SAW devices based on such films need to be considered. The unavailability of deposited LN films boosted the development of single-crystal films by polishing or crystal ion slicing (Smart-cutTM) of industrially available LN wafers and wafer bonding techniques.¹¹⁻¹³ Although, high acoustic velocities can be attained in these hybrid structures, their fabrication is time consuming and expensive. ZnO films on sapphire substrates are also considered for these purposes¹⁴ however, the electromechanical coupling of ZnO is limited.

LN phase exists over a large compositional range (from 46.5 mol% to 50.5 mol% of Li_2O) and LN physical and compositional properties are extremely dependent on the Li_2O nonstoichiometry.¹⁰ Thus, the Li composition within the films has to be controlled with precision, around 0.2 mol%, in order to obtain reproducible physical properties¹⁵ (such as coercive field, acoustic velocity, K_s^2 , etc.) and to meet the requirements on frequency and phase velocity control ($\pm 0.20\%$).¹⁶ Li_2O is also a volatile component at deposition temperatures of LN films (above 900 K). The fabrication of high quality LiNbO_3 films is complicated by the difficulty to control Li_2O composition and consequently the composition and physical

properties of the films.¹⁰ So far, large-scale production of films with physical properties suitable for the targeted applications is not available. The growth of LN films is studied since 70's but Li nonstoichiometry was not optimized and controlled. Li is a very light element and its composition is difficult to measure by direct analysis methods.¹⁰ In most of literature reports, authors claimed about single phase and even stoichiometric films using compositional analysis methods with precision not better than $\pm 10\%$.¹⁰ Recently, the methods of compositional analysis were ameliorated considerably.¹⁷⁻¹⁹

In our work, LN films with controlled Li composition were deposited by means of pulsed injection metalorganic chemical vapor phase deposition. The propagation velocities and electromechanical coupling of SAW resonators, based on optimized Z-LN/C-Sapphire films, with operational frequencies in the range of 3.5 -11 GHz have been studied from both theoretical and experimental points of view.

Hereafter (X,Y,Z) is an orthogonal reference system where Z is parallel to the C-axis and X—to the A-axis, which is taken perpendicular to the mirror plane of the 3m point group. High quality epitaxial Z-axis oriented LN films on C-sapphire substrates were deposited by pulsed-injection metalorganic chemical vapor deposition (PI MOCVD). More details about deposition conditions can be found in Ref. 17 and 20. The thickness of LN films was 458 ± 6 nm (measured by means of spectroscopic ellipsometry). The root-mean-square film roughness was around 6.5 nm as determined by means of atomic force microscopy. Z(XY)Z Raman spectra were collected by using a S&I MonoVista Raman spectrometer with excitation at 532 nm. Raman modes were identified according to the assignment given in Ref. 21. The spectra were calibrated by measuring the spectra of Z-LN single crystal with congruent composition (48.34 mol% of Li_2O) for an equivalent polarization configuration. Methods used to estimate the residual stresses and the Li_2O nonstoichiometry by means of Raman spectroscopy analysis can be found in Ref. 17. The linear relationship between Li nonstoichiometry and Raman mode dampings were identified by Scott et al.²² The spectra were reduced by Bose distribution and fitted using independent damped harmonic oscillator spectral profiles and a linear baseline. The epitaxial quality (rocking curves and ϕ -scans) of the films was studied with a Bruker D8 Discover diffractometer with $\text{Co K}\alpha$ radiation (1.79026 Å).

Two types of single-port resonators, able to excite SAW with wavelengths, λ , of 1 μm (allowing to attain C-band frequencies) and 1.4 μm (representing the main stream of SAW industry), were designed. The single-port resonators consisted of thirty aluminium IDT pairs and twenty aluminium electrode mirrors on each side of the transducer. These resonators were fabricated by using electron-beam lithography. The thickness of said Al electrodes, deposited by evaporation, was 50 nm and an additional 200 nm Al layer was deposited by RF sputtering on the pads for reliable tip-probing measurements. In order to find out theoretically K_s^2 and resonant frequencies of single-port SAW resonators, 1D and 2D simulations were performed by combined finite element (FEM)/boundary element analysis.²³ Two propagation directions in LN films were considered: (ZXt)/0° (X-axis) and (ZXt)/90° (Y-axis). The elastic, piezoelectric and dielectric constants of congruent LN were taken from Kovacs et al.²⁴ The resonators were characterized by admittance measurements, using a ROHDE & SCHWARZ Vector Network

Analyzer (VNA). The frequency response was investigated in the range 1-12 GHz. The K_s^2 was estimated from the resonance frequency taken at maximum conductance, f_r , and the antiresonance frequency taken at maximum resistance, f_a :

$$K_s^2 = \frac{\pi f_r}{2 f_a} \tan \frac{\pi f_a - f_r}{2 f_a} . \quad (1)$$

According to XRD analysis, the LN films on C-Sapphire presented single orientation with (0001) planes parallel to the substrate surface. According to XRD analysis, the epitaxial relationship between sapphire substrate and LN film was $(0001)_{LN} \parallel (0001)_{sapphire}$ and $[11\bar{2}0]_{LN} \parallel [11\bar{2}0]_{sapphire}$. The grown films presented very high epitaxial quality: a full width at half maximum (FWHM) of the rocking curve of 0006 LN reflection was of 0.255° (Fig. 1 a inset) and the FWHM of peaks in ϕ -scan of (01 $\bar{1}$ 2) planes was 0.676° (the resolution of diffractometer was of 0.220° and 0.252° for these measurement configurations, respectively). The Raman spectra of Z-LN film and congruent crystal, measured in Z(XY)Z polarization configuration, are compared in Fig. 1 a. The Raman spectrum of the LN film presented only E(TO) modes of LN phase as expected for this polarization configuration and Raman modes of sapphire substrate confirming a single phase composition of the film. The significant shifts of E(1TO), E(3TO), E(4TO) and E(6TO) mode frequencies with respect to those of single crystal are indicating a presence of tensile residual stresses. Residual stresses of 1.0 ± 0.2 GPa in the films were actually estimated from the shift of E(6TO) Raman mode. The damping parameters of Raman modes of the film were comparable to those of the single crystal, indicating that crystalline quality and nonstoichiometry of the films were similar to those of single crystal substrates. Li_2O nonstoichiometry in the grown films was 48.75 ± 0.2 mol% of Li_2O (estimated from the damping parameter of E(1TO) Raman mode by taking into account the stress effect on the damping of this mode¹⁷).

The S_{11} signal as a function of frequency of single-port SAW resonators with wavelength of $1.4 \mu\text{m}$ on 158 nm thick (ZX)-LN/C-Sapphire film ($h/p = 0.23$, where p is the period of IDTs) are given in Fig. 1 b, respectively. The resonators with propagation direction along X presented two resonances at 3.57 GHz and 3.77 GHz with quality factor at resonance, Q , of 420 and 490, respectively. A single resonance at 3.69 GHz was observed in the case of the SAW propagation along Y-axis, with resonance quality factor of 700 and electromechanical coupling of 0.5 %. In the separate scan at higher frequencies up to 8 GHz, it was observed a minor resonance at 5.90 GHz.

The susceptance as a function of frequency in the range of 3 GHz -12 GHz of single-port SAW resonators with wavelength of $1 \mu\text{m}$ on 158 nm thick (ZX)-LN/C-Sapphire films ($h/p=0.32$) and propagation directions along X-axis is presented in Fig. 2 a. In the case of both resonators, two major modes in the range of 4 - 6 GHz and two minor modes at roughly 7 GHz and 11 GHz were observed. The acoustic waves of resonator 2 (R2) presented slightly lower frequencies (4.72 GHz, 5.43 GHz, 6.82 GHz, and 10.92 GHz) than the waves of resonator 1 (R1) (4.77 GHz, 5.45 GHz, 6.96 GHz, and 10.98 GHz). These discrepancies in frequency ($< 2\%$) can be attributed to the local variations of the

thicknesses of piezoelectric and/or electrode films. The electromechanical couplings of the first and the second modes were around 2.7 % and 8 %, respectively (Fig. 2 a). The first mode at 4.72-4.77 GHz presented a resonance Q factor of 220-300 and the second one at 5.43 – 5.45 GHz a Q value in the range 30-40. The mode at 10.98 GHz sounds like exhibiting high losses.

Theoretical simulations were done in order to estimate the theoretical frequencies/velocities and to identify the type of the contributing acoustic modes. The simulated velocities of the acoustic waves excited by using IDTs with wavelengths of 1 μm and 1.4 μm in 158 nm thick (ZXt)/0° LN films on C-sapphire and in bulk (ZXt)/0° LN crystal are summarized in Table 1. The simulations have indicated that four types of modes could be excited for the propagation direction along X-axis of Z-LN film on C-sapphire by using IDTs with $\lambda = 1 \mu\text{m}$: a pure shear mode – Love mode (4.86 GHz), a Rayleigh wave (5.01 GHz), a Leaky Shear Surface Acoustic Wave (LSSAW, 7.59 GHz) and a Leaky Longitudinal mode (LLSAW, 11.17 GHz) with propagation almost collinear to the film surface (Fig. 2 b). LLSAW corresponds to high-velocity partially guided surface acoustic waves, referred also as a high-velocity (HV) SAW in literature.¹⁴ It is important to underline that the frequency of the Love wave was lower than that of the Rayleigh wave (Fig. 2 b) possibly due to mass loading. The mass loading on the Love wave is more significant than that on the Rayleigh wave. The Rayleigh and Love wave velocities are very close at $h/p=0.32$ and thus, these modes present slightly mixed character. This conclusion is supported by the observation of the corresponding electrode/surface motion reported in Fig. 2 b where one can see that the respective displacements seem to present slightly mixed character. In the case of resonators with $\lambda = 1.4 \mu\text{m}$, the frequency of Rayleigh wave (3.63 GHz) was below the frequency of Love wave (3.89 GHz) as expected for waves in the bulk (ZX)-LN crystals (see Table 1). LSSAW were not expected to be excited in bulk specimens. The Rayleigh wave propagates with phase velocity of $\approx 3750 \text{ m}\cdot\text{s}^{-1}$ along X-direction in bulk Z-LN, while its phase velocity was increased to 5010 -5082 $\text{m}\cdot\text{s}^{-1}$ in Z-LN/C-sapphire heterostructure (for $\lambda = 1.0 - 1.4 \mu\text{m}$). The guiding effect of Love wave diminishes quickly with the increase of h/p ratio: it was 5446 $\text{m}\cdot\text{s}^{-1}$ for $h/p=0.23$ and 4860 $\text{m}\cdot\text{s}^{-1}$ for $h/p=0.32$. The guiding effect is particularly strong on the phase velocity of the longitudinal wave: it increases up to 14322 $\text{m}\cdot\text{s}^{-1}$ for $\lambda = 1.4 \mu\text{m}$ as compared to its velocity of 11170 $\text{m}\cdot\text{s}^{-1}$ for $\lambda = 1.0 \mu\text{m}$.

In general, the measured frequencies and phase velocities are in relatively good agreement but experimentally measured values are slightly lower than the simulated ones. The change of Li nonstoichiometry by 1 mol% could induce a change in phase velocity about around 1%.¹⁵ Our thin films had very similar Li content (48.75 mol%) as compared to the congruent crystals (48.34 mol%). Thus, the deviation of experimentally measured frequencies by 2 - 10 % cannot be attributed to the effect of Li nonstoichiometry. As indicated above, the imprecision in the thickness results in frequency deviations below 2%. The film elastic and piezoelectric properties might be also highly affected by the presence of high tensile residual stresses (around 1 GPa), to be confirmed by further measurements.

All acoustic waves were accelerated by the guiding effect in (ZX)-LN film on C-sapphire substrates. However, the acceleration effect differs for different modes. The longitudinal modes are strongly guided

in (ZX)-LN layers on sapphire substrates (experimentally measured phase velocity was $10920 \text{ m}\cdot\text{s}^{-1}$). Unfortunately, the losses due to energy radiation in the substrate makes the application of this mode very limited. In the case of SAW propagation along Y-axis, the Rayleigh wave propagates with no beam steering and maximises its electromechanical coupling whereas Love wave contribution is not observed. However, it presents still moderate electromechanical coupling (0.5 % for $h/p=0.23$) although the propagation velocity was significantly increased ($5166 \text{ m}\cdot\text{s}^{-1}$). The simulated electromechanical coupling as a function of h/p ratio for propagation directions along X- and Y-axis is given in Fig. 1 b (inset). In the case of $h/p=0.23$ and the propagation along Y-axis, the K_s^2 of 0.9% is expected theoretically in a good agreement with our experimental results. One can note, that the K_s^2 decreases reducing h/p . Therefore, a trade-off needs to be done between phase velocities in excess of $5000 \text{ m}\cdot\text{s}^{-1}$, resonance quality factor higher than 500 and electromechanical coupling overpassing 1%. The maximum electromechanical coupling of about 7.6 % can be attained in the (ZX)-LN films on Sapphire by using $h/p=0.61$ - 0.64 in agreement with simulations, reported in literature.³ In order to attain $h/p=0.64$ with the standard period of 700 nm, the thickness of LN film should be around 450 nm. Experimentally, the high-quality Z-LN films with this thickness is difficult to attain due to relaxation of high residual stresses by twins and cracks.¹⁸ Theoretically, the electromechanical coupling of 5.5 % is expected at $h/p=0.32$ for propagation direction along X-axis (Fig. 1 b inset). However, K_s^2 values of 8 % for the Rayleigh wave at $h/p=0.32$ was measured experimentally. Higher K_s^2 values can be partially related to the deviation from the congruent composition towards stoichiometric one and/or due to presence of very high tensile stresses (1GPa). Further investigations are needed to confirm these hypotheses.

To summarize, the guiding effect on the properties of different acoustic modes in (ZX)LN/C- films on Sapphire was studied experimentally and analyzed by theoretical simulations. We have demonstrated an high acoustical performance compatible with filter applications (K_s^2 up to 8%) for SAW devices operating in the frequency range from 3.7 GHz up to 5.3 GHz and based on grown epitaxial (ZX)-LN films on sapphire. High quality factors can be achieved by reducing h/p ratio, which however implies electromechanical coupling reduction, and to take profit from low losses of the sapphire substrate. Extremely high velocities ($10900 \text{ m}\cdot\text{s}^{-1}$) of LLSAW were also measured experimentally in $\text{LiNbO}_3/\text{Sapphire}$ structure (resonance at 10.9 GHz).
