The field- and current-induced magnetization reversal of a Co-Fe-B layer in a perpendicular magnetic tunnel junction (pMTJ) is studied at room temperature. The magnetization switching probability from the parallel (P) state to the antiparallel (AP) state and from AP to P is found to be asymmetric. We observe that this asymmetry depends on the magnetic configuration of the synthetic antiferromagnetic (SAF). The state diagram and the energy landscape are compared for two SAF configurations. We conclude that the asymmetry is due to the inhomogeneity of the fringe field generated by the SAF. Our study highlights the role of the reference-layer fringe field on the free layer’s energy barrier height, which has to be carefully controlled for memory applications.

I. INTRODUCTION

Current-induced manipulation of magnetization has been a subject of great interest since the prediction of spin transfer torque (STT) by Berger [1] and Slonczewski [2] in 1996. It has led to an innovative magnetic memory technology, namely spin-transfer torque magnetic random access memories (STT MRAM). Such devices are composed of magnetic tunnel junctions with electrodes exhibiting a strong perpendicular magnetic anisotropy (pMTJs) [3–6]. In these devices, the switching current is directly proportional to the energy barrier for thermally activated magnetization reversal [6,7]. Indeed, devices composed of materials with large perpendicular magnetic anisotropy (PMA) have been shown to combine both a good thermal stability and exhibit efficient current-induced switching [6–8]. To further improve a STT MRAM device, the switching energy and the switching time still need to be reduced [9,10], both of which depend on the energy barrier. The study and the characterization of the energy barrier is, therefore, crucial for improving the performance of STT MRAM.

Magnetic tunnel junctions are made of a thin insulating layer sandwiched between a free magnetic layer that can be switched and a reference layer. The latter acts as a spin polarizer for the current and gives rise to a dipolar field with a strong out-of-plane component. This magnetic field, also called a fringe field, may create an asymmetry in the magnetization reversal of the free layer [11]. In order to reduce this effect, “synthetic antiferromagnetic” structures (SAF) have been used to reduce the fringe field. The SAF is composed of two magnetic layers antiferromagnetically coupled through a nonmagnetic layer [12–14]. These layers’ magnetizations are antiparallel and thus have a net magnetization close to zero and, to a first approximation, the average fringe field emitted by the SAF is also close to zero. However, the free layer still experiences a dipolar field associated with the SAF, as one layer of the SAF is closer to the free layer than the other. Moreover, the shape and the size of the device also influence the fringe field value and homogeneity [15–17].

Here, the role of the fringe field from the SAF on the free layer switching is studied. First, the probability of nonswitching for the free layer as a function of the voltage and magnetic field switching is obtained. The latter provides information on the energy barrier to thermally activated magnetization switching. The respective effects of a compensated SAF (antiparallel magnetized layers) and a saturated SAF (parallel magnetized layers of the SAF) on the switching probability and the switching state diagram are investigated.

II. EXPERIMENTS

A [Co(0.25 nm)/Pt(0.8 nm)]4/Ru (0.9 nm)/Co (0.3 nm)/
[Co(0.25 nm)/Pd(0.8 nm)]4/Co(0.25 nm)/Pt(0.8 nm)
Co(0.25 nm)/Ta(0.3 nm)/Co-Fe-B(1.3 nm)/MgO(0.9 nm)/
Co-Fe-B(0.8 nm) /capping sample is grown by dc
magnetron sputtering. The Co-Fe-B(0.8 nm) is the free
layer and the [Co(0.25 nm)/Pd(0.8 nm)]14/Co
(0.25 nm)/Pt(0.8 nm)/Co(0.25 nm)/Ta(0.3 nm)/Co-Fe-
B(1.3 nm) is the reference layer. The layers are separated
by a MgO tunnel barrier. The reference layer is antifer-
romagnetically coupled through the Ru (0.9 nm) to the
[Co(0.25 nm)/Pt(0.8 nm)]14 pinning layer. The reference layer
and the pinning layer together form a SAF layer. We are
interested in the switching behavior of the free layer mag-
netization between its two stable states, parallel (P) and
antiparallel (AP) to the reference layer. The SAF is made to
have an antiparallel alignment of the reference and the pin-
nings layers in order to decrease the fringe field. However,
in this study, to test the influence of the fringe field, we
also consider the case where they are parallel. We call these
configurations, respectively, “compensated” (AP) and “sat-
urated” (P). Let us first consider the case when the SAF is
compensated. All measurements presented in this paper are
performed at room temperature.

Figure 1(a) shows the resistance of the pMTJ as a func-
tion of the voltage for the AP to P transition (orange)
and the P to AP (blue) for numerous sweeps. There is a
distribution of switching voltages. From these data, the
probability of nonswitching as a function of the voltage as
shown in Fig. 1(b) can be determined [16]. Our aim is to
deduce the energy barrier associated with each transition
from the corresponding probability of nonswitching as has
been discussed in Ref. [18].

In order to do so, a single energy barrier \( \Delta E(H) \) re-
presenting the thermal stability of a tunnel junction is con-
sidered between the two stable states [19]. Starting
from the Landau-Lifshitz-Gilbert (LLG) equation describ-
ing the motion of the magnetization [20,21], it is possible
to include the thermal fluctuation contribution based on the
pioneering works of Néel [22] and Brown [23]. It has been
shown that the effect of the voltage can be considered as
an effective temperature [24,25]. Following the same idea,
the nonconservative term of the STT is considered as an
effective temperature in the LLG equation. Koch found
then that the experimental values of STT-driven transi-
tion probabilities in spin valves were in good agreement
with this theory [26]. The switching probability in MTJs
can then be theoretically found using the same models.
Values of the parameters needed to characterize the STT
switching in MTJs can be found in the literature. Ab-initio
calculations have shown that in MTJ, the STT nonconser-
tive torque depends linearly on the applied voltage in
pMTJs [27] and this has also been measured and verified
experimentally [28,29].

This leads us to the expression of the nonswitching prob-
bability \( P_m \) in a MTJ that follows for a voltage \( V \) sweep-
ing with a rate \( r (10 \text{ V/s}) \) experiment at fixed field \( H_{app} \)

\[
P_m(V, H_{app}) = \exp \left[ -\frac{1}{\tau_0 r} \int_0^V \exp \left( -\frac{\Delta E_0}{k_B T} \right) \left( 1 - \frac{H_{app} - H_{off}}{H_{sw0}} \right)^\eta \left( 1 - \frac{V}{V_{sw0}} \right) dv \right].
\]

where \( 1/\tau_0 \) is the attempt frequency of the switching (we
have chosen 1 GHz), \( \Delta E_0 \) is the energy barrier of the trans-
ition, and \( \eta \) is a parameter depending on the geometry and
the switching type, taken here as \( \eta = 3/2 \) [19]. \( H_{sw0} \) and
\( V_{sw0} \) are, respectively, the zero-temperature switching field
and the switching voltage and \( H_{off} \) is, in the first approxi-
mation, the mean value of the average perpendicular fringe
field. This equation is set under three main hypotheses:
the measurement is quasistatic, the conservative part of
the STT is neglected, and the Slonczewski spin torque is
considered as an effective temperature.

The voltage sweepings presented in Fig. 1 are repeated
for different fixed fields and using the expression of the
probability of nonswitching, we obtain the dependence of the
energy barrier of each transition as a function of the
applied field \( \Delta E(H_{app}) = \Delta E_0/k_B T (1 - [H_{app} - H_{off}]/
H_{sw0})^\eta \). Figure 2(a) shows the energy barrier dependence
as a function of the applied field for the two SAF config-
urations, compensated on the left (low fringe field) and
saturated on the right (large fringe field). Figure 2(b) dis-
plays the corresponding state diagrams obtained by record-
ing the switching voltage as a function of the applied field
for both transitions and both configurations as described
in Refs. [30–32]. Insets are schematics of the stack mag-
netic configurations. The results presented in Fig. 2 are
obtained for a 70 \times 100 \text{ nm}^2 junction, but similar results
are obtained for various junction sizes, from 60 $\times$ 80 nm$^2$ to 100 $\times$ 240 nm$^2$ (not shown).

For both configurations of the SAF, the state diagram presents an off-set field that we link in a first approximation to the average perpendicular component of the fringe field. We define $\mu_0 H_{\text{off}}$ as the central value of the field hysteresis loop for no voltage. We obtain $\mu_0 H_{\text{off}} = -30$ mT in the compensated configuration and $\mu_0 H_{\text{off}} = 120$ mT in the saturated one. Their positions are noted in Fig. 2 as the vertical black lines. The evolution of the energy barrier as a function of the applied field can be fitted by the above expression, as shown in Fig. 2(a). We observe that the energy barriers for P to AP and AP to P transitions vs applied field vary in opposite senses; they have opposite signs of their slopes for both SAF configurations. They also cross at a certain field. At this field, the energy barriers' switches from P to AP and from AP to P are equal. We expected that the latter field would correspond to the applied field that compensates the average fringe field, which is clearly not the case.

Both state diagrams presented in Fig. 2(b) are centered around the net off-set field value $\mu_0 H_{\text{off}}$. However, there is an asymmetry of the switching voltages between the two transitions. The switching voltage from AP to P is larger than from P to AP. This effect is clearly seen in Fig. 1 as the measurement is done close to $H_{\text{eff}}$. We clearly observe that the nonswitching probabilities also have different dependencies on the voltage.

A strong effect of the SAF magnetic state is observed in both the voltages and field-driven switchings. In the saturated SAF state, the state diagram width is reduced by two thirds and the switching voltages are shifted toward larger positive values for the AP to P transition. These observations indicate that the asymmetry in switching voltages and energy barriers cannot be described with a simple macrospin model; thus, we use micromagnetic simulation to describe our experiments.

### III. Modeling

The software FASTMAG developed at University of California San Diego [33] is used to study the switching process of the free layer at a given applied voltage, a given applied field, and zero temperature. This software uses a finite element method to solve the LLG equation. We compute a 60 $\times$ 80 nm$^2$ MTJ. We also consider a zero fieldlike torque and a coefficient of the Slonczewski term $a_f = 6.37 \times 10^5$ A m$^{-1}$ V$^{-1}$ [34]. The thickness resolution is 1 nm. We also consider the [Co/Pd] and [Co/Pt] multilayers to be one single block. The free layer (1), the barrier layer (gap), and the 1.3-nm Co-Fe-B layer (2) are set to be 1 nm thick each, the Co (0.3 nm)/[Co(0.25 nm)/Pd(0.8 nm)]$_4$/Co(0.25 nm)/Pt(0.8 nm)/Co(0.25 nm) layer (layer 3) is set to be 5 nm thick, and the [Co(0.25 nm)/Pt(0.8 nm)]$_4$ layer (layer 4) is set to be 15 nm thick. The surface exchange coupling between the upper SAF layer and the reference layer is set to $1.242 \times 10^{-3}$ J m$^{-2}$, and that between the two layers of the SAF is set to $-1.242 \times 10^3$ J m$^{-2}$. The remaining stack parameters are shown in Table I [34,35]:

As already demonstrated, in order to reproduce the experimental state diagram using an analytical or numerical modeling, the uniaxial symmetry needs to be broken. In the present computation, we introduce a tilt of 0.6° in the magneto crystalline anisotropy axis that is sufficient to break the uniaxial symmetry [32]. We are able to follow the magnetic configurations during the STT-driven magnetization switching, as seen in Figs. 3(c)–3(f). This allows us to compare the nucleation points of the reversal depending on the transition. In the case of the compensated SAF, the nucleation point depends on the transition; it occurs at an edge for the P to AP transition [Fig. 3(e)] and at the center of the layer for the AP to P transition [Fig. 3(d)]. In the case of the saturated SAF, the nucleations for both transitions occur at the edge of the sample [Figs. 3(e) and 3(f)].
The strength of the dipolar field as a function of the distance from the center of the sample is also plotted in the (a) compensated SAF (AP blue and AP to P (first line) and AP to P (second line) STT-driven switching in the (a) compensated SAF (AP blue, P red) and (b) “no SAF” (AP red, P blue) configurations.

The strength of the dipolar field as a function of the distance from the center of the sample is also plotted in Figs. 3(a) and 3(b) for both SAF states and both transitions. We observe that the strength of the fringe field depends on the configuration of the SAF as intuited before. Also, in both SAF configurations, the stray field is inhomogeneous along the width of the junction. Even in the compensated case [Fig. 3(a)], it is close to zero at the center of the junction and higher at its edges. Since we show in Fig. 3 that the fringe field has a strong influence on the phase diagram, we claim that the peak in the fringe field at the edges of the sample can explain the asymmetry in the energy barrier of the transitions.

IV. CONCLUSION

The influence of the fringe field from the synthetic antiferromagnet on the switching behavior is shown experimentally by measuring the switching probability of the P to AP and AP to P transitions. The observed asymmetry between the two transitions cannot be explained by the presence of a homogeneous fringe field from the SAF. We demonstrate, thanks to micromagnetic simulations, that this asymmetry observed in quasistatic measurements is likely associated with inhomogeneities of the fringe field of the SAF at the edge of the sample. Similar asymmetry has been reported in the “nanosecond” dynamic switching regime for perpendicular MTJ [36]. Those inhomogeneities favor domain nucleation in certain areas of the free layer depending on the transition.
