Mantle upwelling is essential to spreading centre processes, yet there are few constraints on its detailed structure beneath active ridges. Here we use seismic imaging of the East Pacific Rise to show that the isotropic and anisotropic structure of the mantle is rotated beneath the plate boundary. The isotropic structure defines the pattern of magma delivery from the mantle to the crust. We find that between transforms, the tectonic and magmatic segmentation of the rise correlates well with the distribution of mantle melt. The anisotropic structure defines the direction of mantle flow. Mantle flow is rotated nearly 10° anticlockwise of the plate-spreading direction and thus contributes to the transpressive and transtensional tectonics of nearby transforms. We conclude that skew of asthenospheric upwelling and

transport governs segmentation of the East Pacific Rise and variations in the intensity of ridge crest processes.

The origin of tectonic and magmatic segmentation of oceanic spreading centres is controversial. By one view, along-axis differences in ridge crest processes result directly from three-dimensional mantle upwelling¹⁻⁴. Sites of vigorous volcanic and hydrothermal activity are thus thought to overly regions of greater magma supply. Poor knowledge of mantle structure, however, has given rise to diverging opinions on the scale of three-dimensional upwellings²⁻⁶. Alternatively, segmentation of ridge crest processes may be regulated by the tectonic rifting of young lithosphere⁷, and thus not directly linked to the form of mantle upwelling. In this case mantle flow could be either two-dimensional⁸ or three-dimensional mantle upwellings may be less influential owing to efficient along-axis transport of magma, either by viscous flow or diking at crustal depths⁹.

Along the global ridge system, the fast-spreading East Pacific Rise (EPR) between the Siqueiros and Clipperton transforms (Fig. 1) currently offers our best opportunity for revealing the role of the mantle in governing ridge crest processes. There are several reasons for this. This section of the EPR encompasses a full spectrum of rise axis discontinuities, including: two large-offset transforms; large, long-lived (9°03'N) and small, short-lived (9°37'N) overlapping spreading centres (OSCs)¹⁰⁻¹²; and smaller scale morphologic³, petrologic^{5,12} and seismic^{6,13,14} discontinuities that are typical of fast-spreading ridge segments. Accompanying these axial discontinuities are well known along-axis variations in seafloor depth, axial high morphology¹⁵, crustal structure and thickness¹⁶⁻¹⁹, lava chemistry^{5,12,20,21}, and seafloor hydrothermal^{22,23} and biologic activity²². These characteristics of the EPR, including the origin of ridge crest segmentation, have been hypothesized to result from the supply of magma from the mantle.

The UNDERSHOOT experiment was conducted to seismically image the crustal and mantle structure between the Clipperton and Siqueiros transforms in order to determine the pattern of magma delivery from the mantle to the crust. Here we present the first images of mantle structure beneath an entire ridge segment bounded by long-lived tectonic discontinuities (Fig. 1). Good image resolution allows direct comparison among the scales of tectonic and magmatic segmentation observed along this section of the EPR with the physical structure of the topmost mantle. Our results allow conclusions to be drawn about the driving and controlling processes for segmentation of fast-spreading ridges.

Experiment Geometry and Tomographic Imaging

The distribution of seismic receivers and sources used to image crustal and mantle structure is shown in Fig. 1. The experiment constrains the structure of the uppermost mantle within 4 km of the Moho and within an area extending 15 km to either side of the rise axis and 230 km along the spreading centre. A three-dimensional model of off-axis crustal structure and thickness is used to analyse the mantle refraction data (see Supplementary Information).

The Pn data provide good spatial sampling of mantle structure throughout the image volume (Fig 2a). Pn travel time residuals plotted by azimuth reveal a $\cos(2\Theta)$ pattern (Fig. 2b), a signal indicative of azimuthal seismic anisotropy. The azimuth of anisotropy (i.e., the fast direction for Pn propagation) is $N73^\circ E \pm 1^\circ$ (see Supplementary Information). Tomographic inversions, discussed below, confirm this result. The azimuth of anisotropy is rotated 9° anticlockwise with respect to the predicted spreading direction²⁴ ($N82^\circ E$). Plotted by rise crossing point, Pn travel time residuals show evidence for anomalously low and variable upper mantle velocities (Fig. 2c). The average isotropic velocity that best fits the Pn data (7.6 km/s) is less than typical upper mantle velocities, whereas delays are greater

toward the centre of the transform-bounded segment and less within 20 km of the transforms.

Tomographic inversion (see Supplementary Information) of Pn travel time data reveals a mantle low-velocity zone (MLVZ) that is segmented on a scale comparable to tectonic offsets of the EPR (Fig 1). The MLVZ decreases in amplitude toward each transform, in agreement with the decrease in mean Pn delays (Fig. 2c). Between transforms, the MLVZ follows two en echelon trends that are orthogonal to the azimuth of seismic anisotropy (Fig. 1b, green lines). The en echelon trends are offset in a right lateral sense and rotated anticlockwise with respect to the axis of plate spreading. Due to this rotation, much of the MLVZ is not centred beneath the axial neovolcanic zone. Beneath and immediately north of the OSC the MLVZ steps rightward, defining a geometrically complex transitional region that connects the en echelon trends of the MLVZ. The transitional region, located between $9^{\circ}00'N$ and $9^{\circ}18'N$, is shifted northward of the OSC itself and coincides with a region of thicker crust^{18,19}.

North of the OSC, local minima of the MLVZ occur at intervals of approximately 25 km. Pronounced sub-axial anomalies are located near $9^{\circ}56'N$ and $9^{\circ}44'N$. Equally pronounced anomalies are centred more than 10 km off-axis at $9^{\circ}32'N$ and a few kilometres off-axis at $9^{\circ}15'N$. Between $9^{\circ}15'N$ to $9^{\circ}35'N$ the MLVZ is located 5 to 15 km east of the neovolcanic zone. In the same region, magnetotelluric studies detect anomalously low mantle conductivities 10 to 20 km east of the rise axis²⁵. South of the OSC there is a local minima of the MLVZ near $8^{\circ}43'N$. Within our study area, the most pronounced mantle anomaly occurs beneath the eastern limb of the OSC where several compliance measurements detect near-Moho sills²⁶. The transition of the MLVZ between opposing

limbs of the OSC coincides well with a similar transition of the crustal-level axial magma chamber reflector²⁷ (Fig 1).

We conducted a series of tomographic inversions for fixed models of mantle anisotropy to explore the tradeoffs between isotropic and anisotropic structure. An isotropic mantle results in a large chi-squared travel time misfit (~ 6). Fig. 3 shows that the data misfit is smallest when the azimuth of anisotropy imposed on the tomographic procedure is identical to that estimated from the raw Pn data (Fig. 2b). The data misfit is significantly larger when azimuthal anisotropy matches the predicted spreading direction. A robust result of our analysis is that both the azimuth of seismic anisotropy relative to the spreading direction and the axis of the MLVZ with respect to the plate boundary are rotated anticlockwise by similar amounts.

The Supplementary Information summarizes our analysis of model sensitivity and resolution and details how our current results differ from previously published studies. Therein we show that a ray-tracing error in a previous study of the $9^{\circ}03'N$ OSC²⁸ resulted in an incorrect image.

Skew of Mantle Upwelling and Asthenospheric Flow

The isotropic component of our tomographic image constrains the distribution of melt in the top few kilometres of the mantle. Regions of anomalously low seismic velocities are consistent with higher melt fractions. If melt resides in film-like geometries^{29,30}, then our results can be explained by the presence of 1-3% melt (see Supplementary Information); melt fractions would be greater if distributed anisotropically or if melt pockets are more spherically shaped. We attribute the MLVZ to a region of melt accumulation that lies beneath the base of newly formed oceanic crust and that overlies the melt production region

located at depths of several tens of kilometres. By this view, the axis of mantle upwelling that gives rise to decompression melting is skewed with respect to the plate boundary.

The anisotropic component of our model constrains the direction of shallow mantle flow. This is because the maximum compressional wave speed for single crystal olivine parallels the crystallographic a-axis and deformation of mantle peridotites preferentially aligns the a-axis in the flow direction³¹. We conclude that the direction of shallow mantle flow is skewed by 9° with respect to the plate-spreading direction. The transport of asthenosphere away from the EPR and the axis of decompression upwelling are thus rotated anticlockwise in a coherent manner (Fig. 1).

The rotation of mantle flow beneath the EPR is in the same direction as recent changes in the Euler pole for Pacific-Cocos plate motion, which has been progressing anticlockwise for the past several million years³². Ongoing changes in plate kinematics³², however, are lagging behind the current direction of asthenospheric flow. We propose that the skew of mantle flow beneath the EPR is one of the driving forces for changes in plate boundary kinematics. Specifically, basal tractions imposed by mantle flow are contributing to anticlockwise changes in the spreading direction and the transpressional and transtensional tectonics of the Clipperton and Siqueiros transforms³², respectively (Fig. 4). The lag of the rigid plate system relative to the viscous asthenosphere indicates that transpressive transforms, such as the Clipperton, limit the rate at which plates adjust to changes in plate driving forces³³.

Relation of Ridge Crest Segmentation to Mantle Structure

Our study shows that the tectonic segmentation of the EPR correlates well with the pattern of melt delivery from the mantle to the crust. Near transforms or first-order offsets of the

ridge crest³, the increase in seismic velocities is consistent with a decrease in the amount of melt at near Moho depths and possibly a decrease in temperature. Toward the Siqueiros transform the increase in seismic velocity is most pronounced, consistent with the observed decrease in crustal thickness¹⁹.

Between transform offsets, the EPR is structurally segmented by OSCs or second-order ridge crest discontinuities³. The right-stepping 9°03'N OSC occurs near the ends of en echelon segments of the MLVZ, or where the axis of mantle upwelling is sheared in a right-lateral sense. We suggest that the large-scale rotation of mantle upwelling, with respect to the current Euler pole of Pacific-Cocos plate motion, governs the formation and evolution of the OSC (Fig. 4). In this view, mantle upwellings organize into en echelon segments and large-offset OSCs provide an accommodation zone that transitions the lithospheric plate boundary from one segment of mantle upwelling to another. A previous hypothesis for the origin of OSCs attributes them to variations in the duration, timing or intensity of magmatic pulses that inflate crustal magma chambers and that propagate along the plate boundary, in which case a reduced magma supply is expected near second-order discontinuities⁴. An alternative model infers that OSCs are entirely lithospheric features that form in response to changes in plate motion⁷. We conclude that the segmentation of the EPR by OSCs is a direct result of en echelon upwelling at mantle depths. However, OSCs do not occur near regions of reduced magma supply nor is their evolution related to along-axis migration of magmatic pulses away from centres of replenishment toward magma-starved discontinuities. We propose that OSCs form because the geometry of the rigid plate system is inconsistent with the underlying orientation and geometry of asthenospheric upwelling. As the pattern of mantle upwelling evolves, OSCs will respond to maintain their positions where the axis of upwelling is sheared in the cross-axis direction. We predict that both the size and the sense of offset of an OSC, as well as its

propagation history, will be related to the underlying and evolving pattern of mantle upwelling.

Between transforms and OSCs the EPR is subtly segmented at a scale of ~ 25 km, referred to as third-order or volcanic segmentation^{3,34}. Multidisciplinary studies reveal that volcanic segments are chemically, structurally and geologically distinct. Petrologic data show that lavas erupted within volcanic segments are compositionally similar, yet differences in lava chemistry between volcanic segments can be pronounced^{5,12}. Geophysical studies indicate that the centres of volcanic segments are associated with a more pronounced magmatic system at mid- to lower-crustal depths, and elevated temperatures within a thermal boundary layer that connects the magmatic and hydrothermal systems^{6,14,35}. Near the boundaries of volcanic segments, seismic reflection and tomographic imaging detect abrupt changes in mid- to upper-crustal structure^{6,13,14,35,36}. Lastly, seafloor mapping shows that volcanic and tectonic features are also segmented at this scale³⁴. The structure of the MLVZ correlates well with previous indicators of third-order segmentation, supporting the hypothesis that volcanic segmentation of the EPR is inherited from variations in mantle melt delivery^{5,6,37}. We note that the spacing of volcanic segments is similar to that of diapirs mapped in the Oman ophiolite^{38,39}. Additional studies will be necessary to determine if this is a coincidence or the result of dynamic upwelling.

Relation of the Intensity of Ridge Crest Activity to Skew of Mantle Upwelling

We find that the state of volcanic and tectonic activity along the ridge correlates with the cross-axis distance to a centre of mantle melt delivery. Above rise-centred delivery of mantle melt (e.g., $9^{\circ}50'N$), lavas are young and fissure density is decreased^{22,40,41}. Where mantle melt arrives off axis (e.g., $9^{\circ}30'N$), older lavas and increased fissuring characterize

the axial high. Within our study area, the oldest lavas and the highest density of fissured seafloor^{22,41} is found where the MLVZ is farthest from the rise (9°20'N). Axial eruptive styles also differ, with larger volume, longer duration flows inferred where off-axis delivery of mantle melt occurs⁴². These relations suggest that shorter repose times and smaller eruption volumes may typify volcanoes fed by rise-centred delivery of mantle melt.

The vigour of hydrothermal venting also correlates with the pattern of magma delivery. In regions of rise-centred delivery, high-temperature hydrothermal venting is associated with recent volcanism and vent-supported biologic communities are abundant^{22,40,41}. Either more mature or non-existent high-temperature venting and a general decrease in the abundance of vent-supported biota^{22,40,41} is observed where mantle melt arrives off axis. A transition from on- to off-axis delivery of mantle melt occurs near 9°37'N, where a ridge discontinuity separates a volcanic section of the axial high from a tectonic one and demarcates a significant hydrothermal boundary¹². North of 9°37'N, lavas are less evolved (higher MgO content), eruption temperatures are >1190°C, hydrothermal venting is commonly >350°C and vent fluids are consistent with derivation from the vapour phase of phase-separated fluids^{12,23}. In contrast, south of 9°37'N where mantle melt is delivered off axis, basalts are more evolved (lower MgO), eruption temperatures are <1190°C, hydrothermal venting temperatures are <325°C and vent fluids are derived from the brine phase of phase-separated fluids^{12,23}.

Magma Plumbing and the Segmentation of the EPR

Three significant new findings of our study are that: (i) mantle upwelling and asthenospheric flow are skewed beneath the plate boundary, thus the delivery of mantle melt is frequently not centred beneath the rise; (ii) the 9°03'N OSC, a second-order discontinuity of the EPR, occurs where en echelon segments of mantle upwelling are offset

in the cross-axis direction, and (iii) between first- and second-order discontinuities the cross-axis offset between a centre of mantle melt delivery and the neovolcanic zone correlates with the intensity of rise crest volcanic, hydrothermal, and tectonic activity. Building on these results we propose a new model of magmatic segmentation beneath fast-spreading ridges, illustrated in Fig. 4. In our model the skew of mantle upwelling beneath the plate boundary governs second-order segmentation of the EPR and the intensity of geologic processes occurring within third-order or volcanic segments. Above we discussed the implications of our results for transforms and OSCs.

Away from OSCs and transforms, volcanic segments receive mantle-derived melt from more-or-less equally spaced centres. In contrast to previous hypotheses, rise-parallel variations in ridge processes are not simply a function of magma supply or the along-axis redistribution of magma away from a mantle source^{3,4,9}. Instead, the cross-axis offset between a centre of mantle melt delivery and the associated axial volcano causes axis-parallel changes in ridge crest processes. We illustrate our magma-plumbing model with two cross-sections (Fig 4). One is through a rise-centred site of mantle melt delivery and a volcano characterized by frequent extrusive volcanism and vigorous seafloor hydrothermal and biologic systems; this is representative of the rise near 9°50'N^{22,40} (Figs. 1 and 4). By contrast, the second cross-section is through an off-axis centre of melt delivery that feeds melt to an axial volcano where seafloor eruptions occur less frequently, surface tectonic extension is greater and seafloor hydrothermal and biologic activity are less intense; this is representative of the rise near 9°30'N^{22,40,41}. The contrasting processes at these two sites cannot be attributed to differences in the size and shape of upper crustal magma chambers, which are similar¹³. Nor is it likely that the observed differences in hydrothermal activity can be attributed to near surface permeability, which is expected to be greater where seafloor fissuring and faulting is greater⁴¹. We further rule out magma supply as the

controlling factor since crustal thickness, and by association the long-term magma supply, is similar at each location^{18,19}. We propose that as the cross-axis offset between a centre of mantle melt delivery and the rise crest increases so does the differentiation of magma that is delivered to the volcano. Magmatic differentiation decreases magma temperature, changes its composition, increases its density and enhances the exsolution of magmatic volatiles. We infer that such fundamental changes in the qualities of magma will shape near-surface processes driven by crustal magma chambers.

Our model predicts that magma entering the crustal system from a rise-centred site of mantle melt delivery will have undergone relatively less differentiation. Such magma will be higher in temperature, more buoyant (i.e., higher MgO) and retain a fuller complement of volatiles, thus increasing the breaching of the reaction zone above the axial magma chamber, the exchange of energy between the magmatic and hydrothermal systems and the recurrence of extrusive volcanism that localizes vigorous, high-temperature venting and biologic activity. Sites of rise-centred delivery of mantle melt are most likely to be characterized as volcanically and hydrothermally robust on the basis of surface geology. In the case of off-axis delivery of mantle melt our model predicts that lateral migration of melt at sub-crustal depths will increase igneous differentiation. Crustal magma reservoirs will thus receive melt that is both cooler and denser (lower MgO) relative to reservoirs above rise-centred upwellings. Depending on the degree of differentiation, considerable open system fractionation of magmatic volatiles could occur off axis, in which case the pressurization of a ridge crest magma chamber by volatiles would be less. A decrease in the volatile content of an axial magma chamber should decrease the breaching of the hydrothermal reaction zone and reduce the frequency of volcanic eruptions. In this setting, localized high-temperature hydrothermal venting may be intermittent and lower-temperature, diffuse-flow venting could prevail. Such characteristics are commonly

attributed to magma starvation. In our magma plumbing model two axial volcanoes, or third-order segments, can receive similar volumes of magma, but behave differently (extrusive versus intrusive) because of differentiation-induced changes in magma quality.

Previous models of mid-ocean ridges have commonly assumed that magma supply controls segmentation, that asthenospheric transport parallels the spreading direction and that mantle upwelling and melt delivery is symmetric about the rise axis. Ours is the first study to show large-scale skew of mantle upwelling beneath mid-ocean ridges and as such it renews the debate over the origin and significance of spreading centre segmentation. One implication of our results is that local plate motions alone are not the sole cause of sub-ridge mantle flow. On the contrary, the skew of mantle upwelling and transport can act as a driving force for the tectonic reorganization of the EPR and cause along-axis variations in the intensity of ridge crest processes. We speculate that the skew of the sub-ridge asthenosphere owes its origin to global patterns of mantle flow, which are dominantly controlled by the viscous coupling between subducting oceanic slabs and the surrounding mantle. If this speculation holds, it implies that the flux of slabs into the mantle may be linked to the segmentation of mid-ocean ridges.

Fig. 1. a, Location and geometry of the seismic experiment and **b**, tomographic image of the mantle low-velocity zone (MLVZ) and orientation of mantle anisotropy. **a**, The Clipperton and the Siqueiros transforms bound the study area. Dashed lines shows the location of the plate boundary. Seismic data were collected on 37 ocean bottom receivers from the Woods Hole Oceanographic Institution (white symbols). Twenty of these were Office of Naval Research, three-component seismometers (OBSs) equipped with 1-Hz geophones and a hydrophone; the remaining units were ocean bottom hydrophones (OBHs). The seismic source was the R/V *Ewing's* 20-gun, 8500-cubic-inch (139 litre) air gun array, fired at intervals of 210 s (shot spacing of 500 m) along the tracks indicated by solid black lines. Locations of axial magma chamber reflector from multichannel seismics (MCS) shown in red^{13,16,27}. Black box indicates location of 3-D MCS experiment. **b**, Tomographic image of mantle P-wave velocity; contour interval is 0.1 km/s. Green lines with arrowheads indicates azimuth of seismic anisotropy (see Figs. 2b and 3); black lines with arrowheads indicate plate-spreading direction²⁴. Green lines without arrowheads are perpendicular to seismic anisotropy and indicate locations of en echelon segments of MLVZ. Seafloor compliance measurements indicated by white symbols²⁶; larger white squares are locations where near-Moho melt sills were detected.

Fig. 2. a, Map of the distribution of the 4892 *Pn* ray paths used to image mantle structure. *Pn* data sample the mantle within about ± 15 km of the rise axis. **b**, Mean *Pn* delay plotted by azimuth. Delays are calculated relative to an isotropic model, corrected to 40 km range and binned at intervals of 5° . Vertical bars indicate uncertainty in mean delay as determined by a student t-test (95% confidence interval). Solid line is the best-fit $\cos(2\theta)$ curve. The azimuth of

seismic anisotropy is $N73^{\circ}E \pm 1^{\circ}$. **c**, Mean Pn delay plotted by rise crossing point. Delays are calculated relative to 7.8 km/s and have been corrected for seismic anisotropy (6% with fast axis azimuth of $N73^{\circ}E$). Data are binned at intervals of 10 km and bars indicate uncertainty in mean delay time as determined from a student t-test (95% confidence interval).

Fig. 3. Data misfit following tomographic inversion versus azimuth of seismic anisotropy imposed on starting model. For each inversion, percentage (6%) and azimuth of anisotropy are held fixed. Data misfit is a minimum for an azimuth of $N73^{\circ}E$. Misfit is significantly larger when azimuth of anisotropy parallels the NUVEL-1A spreading direction²⁴.

Fig. 4. Proposed model of magmatic segmentation beneath the East Pacific Rise. **a**, Map view showing plate boundary and tectonic discontinuities (solid black lines), regions of melt accumulation beneath the crust (orange area labelled mush), orientation of mantle flow (green lines with arrowheads) and trend of en echelon segments of the melt accumulation regions (green lines without arrowheads; perpendicular to mantle flow). Thin black line with arrowheads indicates NUVEL-1A spreading direction²⁴. Large, paired arrows indicate regions of transpression (solid) and transtension along the Clipperton and Siqueiros transforms, respectively³². Circles with roman numerals indicate location of cross-sections shown to right. **b**, Two rise-perpendicular sections depicting magma plumbing beneath rise-centred (top) and off-axis (bottom) sites of mantle melt delivery. Above centres of melt delivery magma accumulates at near-Moho depths, presumably within a mush-like compaction layer (orange region). Melt migration paths indicated by red arrows; near Moho melt sills indicated by red ellipses. Small

grey circles depict the exsolution of magmatic volatiles that occurs during differentiation. Sites of rise-centred melt delivery are more likely to be hydrothermally active and resurfaced frequently by extrusive volcanism (plume and smooth seafloor in top section). Sites of off-axis delivery of mantle melt sustain greater amounts of tectonic extension, erupt less frequently and host more intermittent high-temperature hydrothermal activity (rougher seafloor in bottom section).
