#### Abstract 17

Through the years, mineralogical studies have produced a tremendous amount of data on 18 the atomic arrangement and mineral properties. Quite often, structural analysis has led to 19 elucidate the role played by minor components, giving interesting insights into the physico-20 chemical conditions of minerals and allowing the description of unpredictable structures that 21 represented a body of knowledge critical for assessing their technological potentialities. Using 22 such a rich database, containing many basic acquisitions, further steps became appropriate 23 and possible, into the directions of more advanced knowledge frontiers. Some of these 24 frontiers assume the name of modularity, complexity, aperiodicity, and matter organization at 25 not conventional levels, and will be discussed in this review. 26 27

#### **1.** Nature: A treasure-trove for structural complexity 73

The study of the materials formed by Nature, i.e. the minerals, has been always the 74 basis for the greatest breakthroughs in chemistry and solid state physics, including the 75 discovery of new elements and chemical compounds, the construction of the periodic table of 76 the elements and the deciphering of the properties of polarized light (Lima-de-Faria 1990). 77 The observations of the mineral morphologies (crystal faces) led to elaborate theories of the 78 structure of solid matter, which were experimentally confirmed in the first decades of the 20<sup>th</sup> 79 century with the studies on the interaction between X-rays and crystals. The increasingly 80 detailed definition of the physical properties (hardness, tenacity, luminescence, radioactivity, 81 magnetism, electrical and optical properties, etc.) and the compositional and structural 82 characteristics of minerals, as well as the search for natural or synthetic materials with 83 specific mechanical, electrical, magnetic and thermal properties, led to the birth of "materials 84 science" in the middle of the 20th century. The development of materials science was 85 considered as a true technological revolution, a response to precise demands related to 86 economy and industry, and which today is increasingly being used to give answers related to 87 human health and protection of the bio-geosphere. 88

There are about 90 natural chemical elements, which combine to form the ca. 5500 89 known terrestrial and extra-terrestrial mineral species, distinct by chemical composition 90 and/or crystal structure. Minerals represent, in the words of the great Bulgarian mineralogist 91 Ivan Kostov (1913-2004), "...milestones of the history of the Earth and of the Cosmos", as 92 well as a valuable source of information for research on nanotechnologies and innovative 93 materials. They are the product of natural terrestrial and extra-terrestrial laboratories in which 94 laboratory "tests" have been carried out for ca. 4.8 billion years on thermodynamic systems 95 characterized by wide ranges of chemical-physical parameters and evolutionary processes 96 97 (temperature, pressure, activity and mobility of chemical components, electromagnetic radiation, compositional, thermal and baric gradients, gravitational field, etc.). 98

Beside the use of natural compounds as technologically-important materials (Ferraris 99 and Merlino 2005; Depmeier 2009), mineral structures with their inherent complexity have 100 also represented a treasure trove for new discoveries in crystallography. For example, in the 101 field of aperiodic crystallography, the mineral calaverite (Au<sub>1-x</sub>Ag<sub>x</sub>Te<sub>2</sub>, with  $0 \le x \le 0.33$ ) has 102 been the ideal case to begin to shed light on incommensurability in crystals (Goldschmidt et al 103 1931). Later, mineralogy played an important role with numerous examples of mineral 104 structures exhibiting modularities (Ferraris et al. 2008), fast ion conducting properties (Kuhs 105 and Heger 1979), non-commensurate (misfit) layer structures (Makovicky and Hyde 1981), 106 currently known under the name of composite structures, and in providing the first example of 107 a (billion years old) natural quasicrystal (Bindi et al. 2009c), which settled any doubt that 108 could remain on the long-term stability of quasicrystals. 109

In this review we will focus on different aspects of the complexity of mineral 110 structures, including a quantitative definition of crystal-structure complexity (Krivovichev 111 2013a). 112

113

#### 2. Modularity of crystal structures 114

#### **2.1 Introduction** 115

A crystal structure is composed of a very large number of atoms (neutral or ionized) 116 bonded to constitute a three-dimensional, triperiodic network of atoms and of bonds, which 117 can be represented by a graph, where atoms are vertices and bonds are edges. In molecular 118 crystals, the network of bonds can be decomposed into small sub-units (molecules) 119 characterized by stronger bonds (intramolecular bonds), connected by weaker bonds 120 (intermolecular bonds). Moreover, the transition from a state of matter to another (solid to 121

7

liquid, liquid to gas etc.) preserves the molecular entity: ice, water and water vapour are all 122 123 characterized by the same molecular component, the H<sub>2</sub>O molecule, but differ in the way the molecules interact and are arranged one with respect to the other. 124

Inorganic crystals - here we mean really inorganic crystals, not including crystals of 125 metal-organic compounds that, for some inexplicable reason, are today considered in the 126 127 "inorganic" realm - are mainly non-molecular: they differ from molecular crystals in that bringing them to fusion (or sublimation) does not preserve structural unit common to the 128 states of matter, i.e., a molecule. The largest majority of minerals are non-molecular. Fusion 129 of halite, sphalerite, pyrite, "biotite", pyrope... (you name it!) does not produce a liquid with 130 131 intra- and intermolecular bonds.

132 Nevertheless, the structure of inorganic crystals, including minerals, can too be decomposed into elementary building blocks of variable size. Such a decomposition is often -133 but not always – an interpretation of the crystal structures, rather than a physical reality. The 134 most typical example is the smallest and universally known building block: the coordination 135 polyhedron. An octahedron of NaCl<sub>6</sub><sup>5-</sup> or a tetrahedron of ZnS<sub>4</sub><sup>4-</sup> do not correspond to 136 chemical units comparable to a molecule: yet, the polyhedral interpretation of inorganic and 137 mineral crystals is the basis of crystal chemistry since its dawn (Pauling 1929; Wells 1975). 138

Bigger and more complex building blocks occur in modular structures, which are built 139 140 by juxtaposing one or more types of modules. The modules are three-dimensional but have less than triperiodic components (i.e., they are periodic only along one or two directions, or 141 even non periodic at all, in the case of finite components) that can ideally be described as cuts 142 from a structurally and chemically homogeneous parent structure: the archetype. This 143 archetype does not necessarily correspond to a real structure. The most well-known example 144 is certainly that of structures that can be described as based on stacking of layers of equal 145 spheres. The most compact layer, in which each sphere is in contact with six other spheres, 146 has hexagonal symmetry. By stacking identical layers on the top of each other, one gets 147 infinitely many stacking variants, which have maximal compactness if the spheres on adjacent 148 layers are in contact too. This is realized when a sphere of a layer is located on the top of a 149 triangular cavity of the preceding layer. If the position of the spheres on a layer is indicated as 150 A, the two types of triangular cavities in the same layer as B and C (Fig. 1), the stacking 151 variants corresponds to sequences (periodic or non-periodic) of the three letters A, B and C 152 with the same letter never occurring in two successive positions. The archetype is a structure 153 with periodicity of one layer: its stacking sequence is therefore AA and it is not a structure 154 with maximal compactness. It does nevertheless occur in structures with covalent bonds, 155 where the overlap of orbitals determines the relative position of the layers. From this 156 triperiodic archetype, one ideally cuts out a diperiodic layer, whose repetition produces many 157 possible stacking variants. The stacking of layers results in interlayer cavities with different 158 geometry and size, which are then partially occupied by other types of atoms (normally, but 159 not always, less electronegative than the atoms represented by the spheres), leading to a large 160 variability of derivative structures (for a detailed analysis, see Umayahara and Nespolo 2018). 161

162 A wide range of modular structures is known in the literature. The most complete account of modular structures in minerals can be found in Ferraris et al. (2008). The algebraic 163 description of modular structures requires the theory of groupoids (small categories in which 164 every morphism is invertible) and is outside the purpose of this review. Interested readers are 165

referred to the order-disorder (OD) theory (Dornberger-Schiff and Grell-Niemann 1961),
which is the theory of a subclass of modular structures built of diperiodic layers, although
generalisations to rods and blocks have been proposed (Dornberger-Schiff 1964; Belokoneva
2005). A generalisation has been recently introduced by Nespolo et al. (2020).

170

#### 171 **2.2** Symbolic representation of modular structures

Modular structures can be classified as monoarchetypal and polyarchetypal, depending 172 on whether the modules can be viewed as obtained from a single archetype or from at least 173 two different archetypes. The chemical composition of the modules of monoarchetypal 174 modular structures is identical, but the juxtaposition of modules may create or annihilate 175 coordination sites at the interface between two modules. As a consequence, the chemical 176 composition of a series of monoarchetypal structures is not necessarily constant; when it is, 177 then the modular structures are simply polytypes. On the other hand, the chemical 178 composition of a series polyarchetypal structures (polysomes) is by definition variable and 179 180 depends on the ratio between the number of different archetypes building the structure.

In the case of monoarchetypal modular structures, like those based on sphere packings, it is always possible to adjust two modules one next to the other in such a way to form chemical bonds between atoms exposed on the adjacent surfaces of two modules. Depending on the number of possible relative orientations and positions, the number of possible modular structures may increase significantly. If the coordination site at the interface is not affected by the relative arrangement of the modules, then all the monoarchetypal modular structures based on the same type of module are polytypes<sup>1</sup>.

Let us indicate the archetype as A and a module extracted from it as M. Juxtaposing 188 modules **M** in a way to obtain back the archetype **A** can be represented as  ${}^{a}\mathbf{M}_{na}{}^{b}\mathbf{M}_{nc}$ , 189 where  $n_i$  (i, = a, b, c) indicates that number of modules M needed to span the unit cell of A 190 along the axis *j* of the coordinate system. Clearly, to get back the archetype, all the modules 191 are arranged with the same topology one with respect to the preceding (and following) one. 192 This notation applies to non-periodic modules; if the module is monoperiodic (rod or chain) 193 then the repetition along only two axes has to be specified, e.g.,  ${}^{a}\mathbf{M}_{na}{}^{b}\mathbf{M}_{nb}$  if the module is 194 periodic along c. Similarly, if the module is diperiodic (sheet or layer), then the repetition 195 along only one axis has to be specified, e.g.,  ${}^{c}\mathbf{M}_{nc}$  if the module is periodic along a and b. For 196 example, the archetype of the structures based on sphere packing is simply  $A = {}^{c}A_{1}$ , simplified 197 to  $\mathbf{A} = {}^{c}\mathbf{A}$  because nc = 1, or even  $\mathbf{A} = \mathbf{A}$  if it is understood that the only direction lacking 198 periodicity is taken as axis c of the coordinate system. 199

Different modular structures sharing the same archetype can be obtained if the modules **M** are differently oriented and/or positioned with respect to their orientation and position in the archetype. We can differentiate them by an index in parentheses. Monoarchetypal modular structures can then be represented as  $M(1)_{n1}M(2)_{n2}...M(m)_{nm}$ , where nj is the number of modules M(j) that occur continuously in the structure. In this example we suppose a layer structure, so that only one direction of missing periodicity exists. For a rod structure, a 2×2

15 larger definition of polytypism.

<sup>&</sup>lt;sup>1</sup>According to the official definition (Guinier et al. 1984), polytypes are obtained by "stacking layers of (nearly) identical structure and composition" so that the resulting triperiodic structures "differ only in their stacking sequence". The building modules are clearly requested to be layers, although "a more general definition of polytypism that includes 'rod' and 'block' polytypes may become necessary in the future". Here we adopt this

matrix is in general necessary, to take into account the sequence along the two directions of 206 207 missing periodicity. For a structure built by non-periodic modules, a 3×3 matrix would be required. In this section, we fix our attention, for the sake of simplicity, on modular structures 208 built by diperiodic modules (sheets or layers) so that a row matrix of symbols is sufficient to 209 describe it; generalization to structures built by mono-periodic or non-periodic structures 210 211 simply requires adding one or two dimensions to the symbol matrix.

For the sake of simplicity and without loss of generality, let us go back to the case of 212 packing of equal spheres. The three most common polytypes, the hexagonal close packing 213 (hcp) or 2H, the cubic close packing (ccp) or 3C, and the double hexagonal or 4H, correspond 214 215 to the sequences AB, ABC and ABAC, respectively. Accordingly:

 $2H: \mathbf{M}(1) = \mathbf{A}, \mathbf{M}(2) = \mathbf{B};$ 

3C: M(1) = A, M(2) = B, M(3) = C;

 $4H: \mathbf{M}(1) = \mathbf{M}(3) = \mathbf{A}, \mathbf{M}(2) = \mathbf{B}, \mathbf{M}(4) = \mathbf{C}.$ 

•

- 216
- 217 218
- 219
- 220

The same orientation and position can occur in different places in a single period, as in 221 the example 4H above. A somewhat more complex example is that of covellite, CuS, for 222 which the sequence of sulfur atoms is ACAABA (copper occupies some of the cavities 223 224 formed by stacking of layer of sulfur; Umayahara and Nespolo 2018), or, by a shift of the origin, AACAAB<sup>2</sup>, so that its symbolic representation is  $M(1)_2M(2)M(1)_2M(3)$ , where M(1)225 = A, M(2) = C, M(3) = B. 226

The structure of the interface between two modules also plays a role not only in the 227 classification of modular structures, but also for its stability. Extracting modules from an 228 229 archetype and rearranging them in order to obtain a new, different structure opens the possibility of a modification of the inter-module coordination. Let us indicate as I(i/i) the 230 intermodule region between modules i and j: the modular structure can then be represented as: 231 232

233

234

$$[\mathbf{M}(1)\mathbf{I}(1/1)_{n_{1}-1}]\mathbf{M}(1)\mathbf{I}(1/2)[\mathbf{M}(2)\mathbf{I}(2/2)_{n_{2}-1}]\mathbf{M}(2)\mathbf{I}(2/3)....\mathbf{I}(m-1/m)\mathbf{M}(m)_{n_{m}}\mathbf{I}(m/1).$$
 (1)

Let us again analyse a few examples of structures based on the stacking of spheres. The 235 interlayer region between two layers with different position (A and B, B and C, C and A), 236 contains two types of tetrahedral sites, with the triangular basis parallel to the layer and the 237 fourth, apical corner oriented along the stacking direction (the sites are noted  $T^+$  and  $T^-$ 238 depending on whether the apical tetrahedron points along the positive or negative sense of the 239 axis corresponding to the stacking direction) and an octahedral site whose opposite triangular 240 faces are in the layers (noted O) (Fig. 2). The interlayer region between two layers with the 241 same position (A and A, B and B, C and C), contains two types of trigonal pyramidal sites, 242 that we will indicate as  $P_1$  and  $P_2$ , respectively (Fig. 3). 243

244

• Nickeline, NiAs: 2H stacking with the octahedral cavities occupied: COBO. M(1) = C, 245 M(2) = B, I(1/2) = I(2/1) = O.246

<sup>18</sup>  $^{2}$  The sequence of layers does not impose a choice of the origin, which is instead restricted once the spacegroup type of the crystal structure is specified. 19

- Sphalerite, ZnS: 3C stacking with the T<sup>+</sup> cavities occupied:  $AT^+BT^+CT^+$ . M(1) = A, 247  $M(2) = B, M(3) = C, I(1/2) = I(2/3) = I(3/1) = T^+.$ 248 • Molybdenite, MoS<sub>2</sub>: BP<sub>1</sub>BCP<sub>1</sub>C. M(1) = M(2) = B, M(3) = M(4) = C, I(1/1) = I(2/2)
- 249
- =  $P_1$ , I(1/2) = I(2/1) = [] (where ] indicates empty interlayer).
- 250 251

252 When the intermodular region is constant, all the I(i/j) can be simply replaced by I, as in the examples of nickeline and sphalerite. 253

The range of modular structures that can be obtained from a single archetype is actually 254 wider than what is suggested by the examples above. Identical modules obtained from the 255 256 same archetype can be differently oriented with respect to the orientation in the archetype, and 257 this modifies, sometimes profoundly, the interface.

A number of modular structures composed of two (possibly more) types of modules are 258 also known. They are called *polyarchetypal* because each type of module corresponds to a 259 different archetype. A polyarchetypal modular structure can occur if the interface between the 260 261 two types of modules is compatible with the formation of chemical bonds. This requirement limits the possibilities of polyarchetypal crystal structures; putting two modules one next to 262 the other does not necessarily results in a configuration compatible with the formation of 263 chemical bonds. Polyarchetypal modular structures are known as *polysomatic structures* 264 265 (Thompson 1978). The symbolic representation in Eq. (1) applies to polyarchetypal modular structures too; the only difference with respect to the case of monoarchetypal modular 266 structures is that the modules M(j) are obtained from two or more different archetypes. 267

The scope of this brief survey being necessarily limited, we have chosen to analyse in 268 details mono- and diarchetypal modular structures where the building blocks are di-, mono- or 269 270 non-periodic modules ideally obtained from the TOT layer of phyllosilicates.

271

#### 272 2.3 Modular structures whose archetype are phyllosilicates

Phyllosilicates are layer minerals built by stacking layers of different structure and 273 composition. Depending on the type of layers, several phyllosilicate archetypes exist. 274

Phyllosilicate layers are composed of two types of sheets: 275

1.corner-sharing tetrahedra (T hereafter) centred around a small cation (mainly silicon, 276 partially substituted by aluminium, iron, titanium); the corners are occupied by oxygen atoms 277 278 (Fig. 4a);

279 2. sheets of edge-sharing octahedra (O hereafter) centred around various cations (aluminium, magnesium, iron, manganese, titanium, lithium); the O sheet alone occurs in 280 hydroxide minerals like brucite, Mg(OH)<sub>2</sub>, in which all the octahedra are occupied (Fig. 4b), 281 and gibbsite, Al(OH)<sub>3</sub>, in which one third of the octahedra are vacant (Fig. 4c). 282

In the T sheet, all the tetrahedra have the same orientation with respect to the direction 283 of stacking. Three of the four vertices define the basis of the tetrahedra and the anions on 284 these vertices, called the basal oxygen atoms O<sub>b</sub>, define a geometric plane. The fourth corner, 285 occupied by the apical oxygen atoms, connects the T sheet with the O sheet, by replacing the 286 287 corresponding OH group. In the so-called Pauling model the T sheets have hexagonal symmetry. In the real structure, because of the difference in the lateral dimensions of the T 288 and O sheets, tetrahedra rotate around [001] by an amount that depends mainly on the 289 290 chemical composition but also external conditions like temperature and pressure, so that the

symmetry of the T sheet is reduced to ditrigonal. The model that takes into account this 291 rotation is known as the trigonal model (Nespolo et al. 1999). 292

In the O sheet, the OH groups can be replaced not only by the apical oxygen atoms of 293 the T sheet, also by fluorine, chlorine, oxygen atoms not belonging to the T sheet, or, much 294 more rarely, by sulfur. In the real structure of minerals, these sheets are deformed with respect 295 296 to their ideal configuration: tetrahedra are actually disphenoids, octahedra are actually trigonal antiprisms (eigensymmetry  $\overline{3}m$ ) or metaprisms (eigensymmetry 32) or even polyhedra with 297 lower symmetry. However, for the sake of simplicity, we retain their idealized description. 298 Readers interested in the real structure of the phyllosilicate layers can find abundant details in 299 Ferraris and Ivaldi (2002). 300

301

Depending on how the sheets are arranged in the layers, several archetypes are realized.

1. Layer built by one T sheet and one O sheet (TO layer). Depending on whether the 302 nature of the O sheet, the layer is brucitic, like in the serpentine mineral, or gibbsitic, like in 303 the kaolinite mineral. 304

305 2. Layer built by one O sheet sandwiched between two T sheets (TOT layer). Depending on the nature of the O sheet and of the interlayer region, a number of minerals are realized: 306 talc (brucitic TOT without interlayer cations), pyrophyllite (gibbsitic TOT without interlayer 307 cations), micas (with interlayer cations), montmorillonites (smectites) and illites (with the 308 309 interlayer region only partially filled with cations).

310

3. A TOT layer alternating with an O sheet, like in the chlorite minerals.

Depending on the distribution of cations occupying the O sheets, phyllosilicates are 311 classified into different families, with a more or less fine classification depending on the 312 purpose of investigation. Here we are interested in the modular structure of these minerals, 313 314 which does not significantly change with the nature of the cations. Therefore, we can simplify the classification to three archetypes, differing by the type of layer (TO, TOT and TOT:O), 315 each characterised by a period of one layer along the stacking direction. In the following we 316 deal specifically with the TOT archetype, which provides a large number of modular 317 structures occurring in nature. 318

In the TOT layer, the two T sheets are actually staggered one with respect to the other 319 by about a/3 in the projection on the (001) plane (Fig. 5a). As a consequence, most of the 320 symmetry operations of the O sheet are not extended to symmetry operations of the whole 321 layer. Only the inversion, one of the two-fold rotations and one of the mirror reflections are 322 (Fig. 5b). Therefore, the interlayer region has trigonal symmetry (ideally hexagonal) whereas 323 the layer symmetry has only monoclinic symmetry. Stacking two TOT layers one on top of 324 the other can be realized in three orientations (six, in the Pauling model) that correspond to 325 the same configuration of the interlayer region but not of the layer. This leads to three (ideally 326 327 six) different mutual orientations of the same pair of layers, i.e., three (ideally six) modular structures with the period of two layers, which are simply polytypes. The same situation 328 occurs for each pair of layers so that with the increase in the period the number of possible 329 polytypes increases significantly. Furthermore, the interlayer region may be empty or host 330 cations and small molecules, which increases the number of modular structures. Finally, a 331 different module, namely a rod, can be extracted from the same archetype, leading to a large 332 number of modular structures which differ for the relative position of these rods along two 333 directions and for the nature of the intermodular region. 334

335

# 336 2.3.1 Layer modular structures

Modular structures where the module is a TOT layer can be represented by Eq. (1) in which all the modules **M** have the same chemical composition and structure but differ for their relative orientation and/or position. These can be identified as follows.

The TOT layer has monoclinic symmetry. The relative orientation of two TOT layers can be specified by the orientation of the unique symmetry direction in each of the two layers. Although in principle infinitely many relative orientations are possible, the ditrigonal (ideally hexagonal) symmetry of the plane of basal oxygen atoms actually restricts these orientations of multiples of 60°, which correspond to orientations under which the coordination sites in the interlayer region is unchanged.

Mapping of one layer onto the adjacent one can be obtained by a twofold rotation about a direction in the interlayer region, followed by a shift along the same or another direction again in the interlayer region. In the following, we will differentiate modular structures based on the stacking of TOT layers in "zero-shift" and "non-zero-shift", depending on whether the shift component of this mapping is absent or present. The zero-shift configuration preserves the coordination sites in the interlayer region, whereas the non-zero-shift modifies it.

In each TOT modular structure, the interlayer region is essentially the same between each pair of layers and can be empty or contain cations, small molecules or more complex components, like the O sheet one finds in chlorites. The archetype is simply A = M, in which the unit cell contains a single layer; two adjacent layers, in successive unit cells, are in parallel orientation and have zero-shift relative position.

358

# 359 2.3.2 Modular structures with empty interlayer region

The simplest modular structures obtained by stacking TOT layers are those in which the 360 interlayer region is empty. Stacking the layers with parallel orientation and with the same shift 361 results in a one-layer period. For zero-shift the result would be the archetype, which however 362 is not realized in nature. The 1A (one-layer period, triclinic) polytype has a non-zero shift 363 between the TOT layers in two successive unit cells. Fig. 6a and 6b show, respectively, the 364 365 structure of talc and of pyrophyllite, which differ by the content of the O sheet (Mg filling all the octahedral cavities vs. Al filling two third of them, respectively). The lower T sheet has 366 been removed for the sake of clarity. Fig. 7a and 7b show a different section of the same 367 structure, with two adjacent T sheets belonging to two successive TOT layers, from which the 368 369 O sheets have been removed. The ditrigonal cavities (ideally hexagonal) have parallel orientation but are shifted by about a/3 for talc (0.2968a, Fig. 7a) and about 1/10 along the 370 [120] direction for pyrophyllite (Fig. 7b). Both talc and pyrophyllite occur also in a different 371 polytype, 2M (two-layer period, monoclinic), where again adjacent layers show non-zero 372 shift. The majority of polytypes are however disordered, i.e., without a periodicity along the 373 374 stacking direction. This is the result of the weak van der Waals bonds between successive layers, which are not interlocked by the presence of cations or small molecules. 375

376

#### 377 2.3.3 Modular structures with cations in the interlayer region

The presence of cations in the interlayer region is characteristic of micas. Depending on 378 whether the cations are mono- or divalent, micas are classified in *true micas* and *brittle micas*. 379 These cations lock successive TOT layers in zero-shift configuration, but the relative rotations 380 381 of  $n \times 60^{\circ}$  (*n* integer) result in a large number of polytypes. The strong ionic bonds between the cations and the basal oxygen atoms of the tetrahedra belonging to two adjacent TOT layers are 382 considered responsible for the occurrence of periodic polytypes with variable, sometimes very 383 large, periodicities (Nespolo and Ďurovič 2002). 384

In the Pauling model, the six  $n \times 60^{\circ}$  orientations all correspond to the same 385 configuration of the interlayer region. In the trigonal model, this sixfold degeneration is partly 386 resolved. Even  $(2n \times 60^\circ)$  orientations result in a staggered configuration of the basal oxygen 387 atoms (Fig. 8a, phlogopite-1*M*: Redhammer and Roth 2002), whereas odd  $[(2n+1)\times60^{\circ}]$ 388 orientation in an eclipsed orientation (Fig. 8b, phlogopite-20: Ferraris et al. 2001; and Fig. 8c, 389 390 lepidolite- $2M_2$ : Guggenheim 1981). This difference is considered one of the reasons for the higher occurrence frequencies of polytypes showing even orientations. Furthermore, minerals 391 with inhomogeneous occupation of the octahedral sites, in particular those where one of the 392 three independent sites is empty, result in a tilting of the tetrahedra which makes the plane of 393 394 the basal oxygen atoms no longer flat but corrugated, and this further destabilizes odd-rotation configurations (Fig. 9). 395

Partial occupation of the interlayer region occurs in some clay minerals like illite (K-396 poor muscovite) and montmorillonite (showing incomplete occupation of the interlayer region 397 by cations like  $Na^+$  and  $Ca^{2+}$ ). The configuration of the interlayer region in illite is essentially 398 399 the same as in muscovite, whereas that in montmorillonite, characterized by a lower occupancy in the interlayer region, is closer to that of pyrophyllite. 400

401

#### 402 2.3.4 Modular structures with an O sheet in the interlayer region

403 The alternate sequence of TOT layers and O sheets is typical of chlorite. The presence of an O sheet in the interlayer region leads to hydrogen bonds between the hydroxyl groups 404 on the surface of this sheet and the basal oxygen plane of the TOT sheets next to it. This 405 network of hydrogen bonds results in a non-zero-shift of successive TOT layers. Fig. 10 406 407 shows the 1*M* polytype of chlorite (Zanazzi et al. 2007): successive TOT layers are equally 408 oriented but shifted by 0.42a.

Hydrogen bonds are stronger than van der Waals bonds, but definitely weaker than ionic 409 bonds. This partly explains the scarcity of periodic polytypes in chlorite with respect to micas. 410 411

412 2.3.5 Rod modular structures

The TOT layer can be imagined as built by three separate sheets (two T sheets and an O 413 sheet) that are attached one on the top of the other. The apical oxygen atoms of the T sheets 414 replace two thirds of the hydroxyl groups of the O sheets. The remaining OH groups allow to 415 416 differentiate the octahedral sites. The primitive unit cell contains three octahedral sites: one 417 has the OH groups in *trans* configuration, the two others in *cis* configuration (Fig. 11).

The TOT layer can be cut in rods with different widths, which can the assembled 418 together to produce a wide range of minerals. The juxtaposition of two rods implies a 419

positional, but no rotational, degree of freedom, contrary to the case of layers, which are 420 421 diperiodic. The result depends on several factors.

- The width of the rod, which is measured by the number of full octahedra it contains; a 422 rod *n*-octahedra width is indicated as  $R_n$ . Fig. 12 shows rods  $R_5$  and  $R_8$ . Clearly, 423 moving along a, the boundaries of a rod pass either through the oxygen atoms / 424 hydroxyl groups (defining full octahedra) or cations (cutting through the octahedra). 425 The former are taken as measure of the width of the rod. 426
- The occupation of the regions between pairs of rods, along the two directions of 427 missing periodicity. 428
- The bonding scheme between pairs of rods. 429
- Because the modules are monoperiodic, Eq. (1) has to be generalized to a  $2 \times 2$  matrix 430 form. The T and O sheet in the TOT layer become there the T and O chain of the TOT  $(R_n)$ 431
- rod. The TOT phyllosilicate archetype can be written as 432
  - $R_n$
- 433

where  $\Box$  represents the empty region between successive layers. The first line represents the 434 layer itself; indeed, a layer can be interpreted as an infinite juxtaposition of rods *n*-octahedra 435 436 width for any value of n. The second line shows the interlayer region is empty. Modular structures built by the juxtaposition of rods can be represented by extending the above 437 notation, which however cannot account for the bonding scheme between pairs of rods, which 438 is realized in two ways: 439

- 1. the OH-O<sub>b</sub> scheme, obtained by replacing an hydroxyl group of the O chain by the 440 basal oxygen atom of a neighbouring T chain; 441
- 442 443
- 2. the Ob-Ob scheme, obtained by sharing the basal oxygen atom of two neighbouring T chains.

The following analysis is a schematic version of the publication of Nespolo and 444 Bouznari (2017). Rod modular structures with the OH-O<sub>b</sub> scheme are shown in Figs. 13-15. 445 Fig. 13 shows the structure of amphiboles, which can be interpreted as composed by  $R_5$  rods, 446 periodic along the c axis of the mineral, displaced one with respect to the other along the a447 axis. Exactly the same topology occurs in jimthompsonite, which is built by rods R<sub>8</sub> instead of 448  $R_5$  (Fig. 14). The structure of the two minerals can be represented as 449

- $X \square X$  $R_{i}$
- 450
- $X \square X$  $R_{n}$

where  $\Box$  represents empty space, X is a cation, and n = 5 or 8 respectively. Depending on 451 cations occupying the O chain and the nature of the X cation amphiboles are classified in a 452 number of different minerals. In some of these, the empty space ] is sometimes occupied by a 453 monovalent cation, mainly sodium. A similar variation has not been found in jimthompsonite. 454

455 Intermediate structures do exist as well. Fig. 15 shows the structure of chesterite, which can be schematically represented as 456

> $X \square X$  $R_{5}$

$$X \square X = R_s$$

i.e., by an alternation of amphibole-like modules and jimthompsonite-like modules. 458

30

Rod modular structures with the  $O_b$ - $O_b$  scheme are shown in Fig. 16-18. The sequence 459 of R<sub>5</sub> and of R<sub>8</sub> rods is found in palygorskite and sepiolite respectively, where water molecules 460 occur instead of the X cations of amphiboles (Figs. 16 and 17). It can be symbolically 461 represented as 462

- $R_n$ Н,О
- $H_2O = R_n$

A further modular structure is known as well, kalifersite, which shows an alternation of 464  $R_3$  and  $R_6$  modules, i.e., 465

> $R_{3}$

 $R_6$ 

467 (Fig. 18).

468 The symbolic representation adopted here has the advantage of being synthetic and illustrative but does not have the ambition to express the difference in the relative position of 469 the modules. Our purpose here is to point out and emphasize the tight structural relations 470 between minerals that were only partially recognized in the past (Thompson 1978). For a full 471 structural information, one needs a more detailed description; interested readers are referred to 472 Nespolo et al. (2018). 473

474

463

466

#### 2.4 Polyarchetypal modular structures. The example of pyroxenoids 475

Polyarchetypal modular structures are built by the juxtaposition of modules taken from 476 477 two or more archetypes. A large number of examples can be found in Ferraris et al. (2008). Our aim is to illustrate the general principle in the simplest possible way. For that, we restrict 478 our treatment to one of the two series of pyroxenoids, diarchetypal minerals whose modules, 479 although different, can again be obtained from the TOT layer of phyllosilicates (Angel and 480 Burham 1991). 481

Pyroxenoids are metamorphic minerals with variable chemistry and occurrence. They 482 are classified on the basis of two parameters (Takéuchi 1997). 483

- 1. The period along the direction of the T chain, which is of three or more tetrahedra. 484 485 Wollastonite, whose T chain has a period of three tetrahedra, is one archetype. The second archetype is not a pyroxenoid but a pyroxene, whose T chain has a period of 486 two tetrahedra. 487
- 2. The width of the O chain, sandwiched between two T chains, measured roughly 488 perpendicularly to the direction of the T chains, variable between two and three 489 490 cation sites. These sites have only approximate octahedral geometry, but in the following we will treat them as octahedral for the sake of simplicity. 491

Fig. 19a shows the structure of the first archetype, wollastonite,  $CaSiO_3$ , along the b 492 axis. The O chain has a width of three octahedra. Fig. 19b shows the same structure along 493 494 [101]\*, with the cation sites in a ball-and-stick representation instead than polyhedral. The period of the tetrahedral chain is three tetrahedra. The structure of wollastonite can therefore 495 be described as obtained by juxtaposition of TOT rods composed of tetrahedral chains with 496 period of three tetrahedra and octahedral chains three-octahedra wide. These rods can be 497 represented as  $R_{0}^{T} = R_{3}^{3}$ , where <sup>T</sup> indicates the number of tetrahedra defining the period of the 498 T chain and o the number of octahedra defining the width of the O chain. 499

Fig. 20a and 20b show the structure of the other archetype, a pyroxene, (M2M1)SiO<sub>3</sub> (M2 = Ca, Mg, Fe<sup>2+</sup>, Na, Li, M1 = Mg, Fe<sup>2+</sup>, Al<sup>3+</sup>, Fe<sup>3+</sup>) along [001] and along [101] respectively. The larger site (white polyhedron in Fig. 20a, usually indicated as M2 in the literature) does not have an octahedral geometry but in this treatment we approximate it to an octahedron. The rods building the structure of pyroxenes can therefore be represented as  $R^{T}_{O}$  $= R^{2}_{2}$ .

Fig. 21 shows the structure of rhodonite group minerals (Shchipalkina et al. 2019), CaMn<sub>4</sub>Si<sub>5</sub>O<sub>5</sub>, seen along [100]\*. This structure is composed by a regular alternation of wollastonite-like slabs and pyroxene-like slabs. The slabs are cut from the rods and are therefore non-periodic. We can represent it as  $S_{3}^{3}S_{2}^{2}$ , where  $S_{0}^{T}$  stands for "slab" O octahedra thick obtained from the chain  $R_{0}^{T}$ .

Fig. 22 shows the structure of pyroxmangite, MnSiO<sub>3</sub>, along [100]\*, which is composed by a regular alternation of one wollastonite-like slabs and two pyroxene-like slabs. It can be represented as  $S_3^3(S_2^2)_2$ .

Fig. 23 shows the structure of ferrosilite-III, FeSiO<sub>3</sub>, along [110]\*, which is composed by a regular alternation of one wollastonite-like slabs and three pyroxene-like slabs. It can be represented as  $S_3^3(S_2^2)_3$ .

These five minerals can be seen as representative of a potentially large family of diarchetypal modular structures, whose general member is  $S_3^3(S_2)_n$ . Members known so far correspond to n = 0 (wollastonite, first archetype), n = 1 (rhodonite), n = 2 (pyroxmangite), n= 3 (ferrosilite-III) and  $n = \infty$  (pyroxene, second archetype). The period of the T chains is 2n+3 tetrahedra; for the pyroxene archetype,  $n = \infty$  indicates the absence of wollastonite-like slabs so that the period corresponds to the thickness of a  $S_2^2$  slab, i.e. two tetrahedra.

523

### **3. Information-based analysis of structural complexity of minerals**

### 525 **3.1. Introduction**

The problem of quantifying the complexity of natural and artificial structures is of high 526 importance for modern science that deals with more and more complex systems in the course 527 of its development. Crystals are considered as intuitively simple systems (Bennet 1990), due 528 529 to the periodic character of their structures, and their complexity was the subject of thought for crystallographers at the very beginning of the development of X-ray diffraction analysis. 530 In particular, Pauling (1929) suggested the parsimony rule that states that '...the number of 531 different types of constituents in a crystal tends to be small'. The topic of structural 532 complexity of crystals reappeared in scientific literature many times (see Krivovichev (2013a, 533 2016b, 2017) for historical remarks), but only recently the universal measures were suggested 534 based upon the Shannon information theory (Krivovichev 2012a, b, 2013a, b, 2014, 2016a). 535 Below we formulate the basic principles of this method by considering an *n*-dimensional 536 crystal structure in order to cover both classical crystals and those that can be described using 537 superspace approach. 538

539

### 540 **3.2. Structural complexity measures**

The complexity of a crystal structure can be estimated as the amount of Shannon information per atom (represented by a point),  ${}^{\text{str}}I_{\text{G}}$ , and per unit cell,  ${}^{\text{str}}I_{\text{G,total}}$ , calculated according to the following equations:

544

$${}^{\text{str}}I_G = -i = \mathbf{1} \sum_{i=1}^{k} p \sum_{i=1}^{k} \square p \qquad \text{(bits/atom)}$$
(1),

545

$${}^{\text{str}}I_{G,total} = -v I_G = -v_{i=1} \sum_{i=1}^{p} \sum_{i=1}^{m} p_i \log_2 p_i \quad \text{(bits/cell)}$$
(2)

547

where k is the number of different crystallographic orbits in the structure and  $p_i$  is the 548 random-choice probability for an atom from the *i*th crystallographic orbit, that is: 549

550 551

552

$$p_i = m_i / v \tag{3},$$

where  $m_i$  is the number of points of the crystallographic orbit in the reduced unit cell<sup>3</sup>, and v 553 is the total number of atoms in the reduced unit cell. 554

555 The Shannon information measures are applicable to any crystalline structure that can be characterized by a finite amount of atoms located in a finite amount of space with defined 556 equivalence relation among atomic sites (including trivial symmetry). The two measures of 557 structural complexity,  ${}^{str}I_G$  and  ${}^{str}I_{G,total}$ , reflect upon the two important properties of complexity, 558 size and symmetry of a system. While the parameter  ${}^{str}I_G$  is sensitive to symmetry, the 559 parameter  ${}^{str}I_{G,total}$  is sensitive to both symmetry and the number of translationally independent 560 sites, i.e. the size of a system. 561

The equations (1-3) do not take into account the complexity of bonding network in the 562 crystal structure, which can be accounted for by introducing additional measures (e.g., by 563 including bonds into consideration (see (Krivovichev 2013a) for more details). 564

The equations (1-3) may be used to calculate *information density*,  $\rho_{inf}$ , of a crystal 565 structure as the amount of Shannon information per volumetric unit, e.g. per cubic Ångström: 566 567

568

$$\rho_{\rm inf} = {}^{\rm str} I_{G,total} / V_{\rm red}$$
(4),

569

$$v_{\rm inf} = {}^{\rm str} I_{G,total} / V_{\rm red}$$
(4),

570 where  $V_{\rm red}$  is the volume of the reduced unit cell. The information density is the parameter that can be strictly applied to one unit cell only and not to the whole crystal, since 571 the periodicity condition of a crystal structure would result in the redundant character of all 572 information except for the one contained in a single reduced unit cell. 573

574

#### 3.3. Applications: general overview 575

Krivovichev (2013a, 2014) calculated information-based structural complexity 576 parameters for all known inorganic and mineral structures and classified them according to 577 their  ${}^{\text{str}}I_{G,total}$  parameter value into five groups (bits/cell): very simple (0-50), simple (50-100), 578 intermediately complex (100-500), complex (500-1000), and very complex (> 1000 bits/cell). 579 580 The procedure of the information-based measures of structural complexity calculation in

<sup>&</sup>lt;sup>3</sup> A reduced cell is a primitive (minimal volume) cell satisfying two restrictions on the basis vectors **a**, **b**, **c**: 36 37 1) of all lattice vectors, none is shorter than **a**; of those not directed along **a**, none is shorter than **b**; of those not lying in the **ab** plane, none is shorter than **c**; 2) The three angles between basis vectors are either all acute 38

<sup>39</sup> (type I) or all non-acute (type II).

incorporated into the TOPOS Pro program package (Blatov et al., 2014), which is freely 581 582 available for download.

For minerals, Krivovichev (2013a) provided the following average values of 583 information-based structural complexity measures:  $< {}^{str}I_G > = 3.23(2)$  bits/atom and  $< {}^{str}I_{G,total} >$ 584 = 228(6) bits/cell. However, these calculations were based upon partial structural information, 585 since for many crystal structures of hydrated minerals, the positions of H atoms have not been 586 determined in the original structural studies. For hydrated Ca borates, Pankova et al. (2018) 587 used the procedure of H-corrections by introducing surrogate H sites into the structure data, 588 and this procedure was recently performed for all mineral species known to date 589 (unpublished). The new average complexity parameters for minerals are:  $\langle str I_G \rangle = 3.48(2)$ 590 bits/atom and  $\langle {}^{str}I_{G,total} \rangle = 303(6)$  bits/cell. The increase in the average values is due not only 591 to the inclusion of H atoms into calculations, but also owing to the fact that more and more 592 complex minerals are discovered in nature due to the applications of novel experimental 593 techniques, including high-sensitive area detectors, the use of synchrotron radiation and the 594 advances in electron diffraction methods. 595

596 597

### **3.4.** Most complex mineral structures

Table 1 provides the list of five most complex mineral structures known in April 2020. 598 Ewingite,  $Mg_8Ca_8[(UO_2)_{24}(CO_3)_{30}O_4(OH)_{12}(H_2O)_8](H_2O)_{130}$ , is the Earth's most complex 599 mineral reported so far with the estimated complexity of 23477.507 bits/cell. The mineral was 600 601 found as golden-yellow crystals formed on a damp wall of the old Plavno mine of the Jáchymov ore district, western Bohemia, Czech Republic (Olds et al. 2017), where 602 crystallized from low-temperature uranyl-bearing aqueous solutions. Its crystal structure 603 contains a 54-nuclear (24U + 30C) uranyl carbonate cluster  $[(UO_2)_{24}(CO_3)_{30}O_4(OH)_{12}(H_2O)_8]^{32-1}$ 604 shown in Fig. 24a. Its skeletal representation (Fig. 24b), where each node corresponds either 605 to U (yellow) or to C (grey) center emphasizes the presence of four  $U_3$  triangles (with the U-U 606 distances shorter than 4 Å) that correspond to the trimers of three  $((UO_2)O_5)$  pentagonal 607 bipyramids sharing the same equatorial O atom. Two other building units are the  $[(UO_2)]$ 608  $(CO_3)_3$ ] and  $[(UO_2)(CO_3)_2(H_2O)_2]$  hexagonal bipyramids. The visual complexity of the cluster 609 architecture can further be reduced by leaving only U atoms and the addition of the U-U links 610 corresponding to the U-U distances in between 4 and 6.2 Å (Fig. 24c). The resulting graph 611 612 can be considered as consisting of four  $U_3$  trimers (U-U < 4 Å) and six  $U_4$  dihedra of two edge-sharing  $U_3$  triangles (U-U = 4.0-6.2 Å). The centers of the trimers and the dihedra 613 (denoted by red and blue circles in Fig. 24c) form tetrahedron and octahedron, respectively, 614 with six tetrahedral edges in correspondence to six octahedral vertices (Fig. 24d). Such a 615 relation between the tetrahedral and octahedral graphs is known in graph theory as an edge-to-616 vertex duality. The octahedral graph can be obtained from the tetrahedral graph  $K_4$  by 617 associating a vertex with each edge of the  $K_4$  graph and connecting two vertices with an edge 618 if the corresponding edges of  $K_4$  have a vertex in common (Gross and Yellen 2006). 619 Therefore, the topology of the uranyl carbonate cluster in ewingite, in addition to its extreme 620 complexity, has the interesting property of being self-edge-to-vertex dual. 621

Morrisonite,  $Ca_{11}[As^{3+}V^{4+}_{2}V^{5+}_{10}As^{5+}_{6}O_{51}]_{2}$ . 78H<sub>2</sub>O, has 13558.354 bits of Shannon 622 information per unit cell and, after ewingite, is the second most complex mineral known so 623 624 far. The vanarsite-group minerals (Kampf et al. 2016, 2020) contain unique and previously unknown type of the V-As POM cluster with the composition  $[As^{3+}V_{12}As^{5+}O_{51}]$ . The cluster 625 consists of twelve (VO<sub>6</sub>) octahedra forming wheel- or corona-shaped unit centered by  $As^{3+}$ 626 cation in a trigonal-pyramidal coordination (due to the stereoactivity of a lone-electron pair) 627 and surrounded by six ( $As^{5+}O_4$ ) tetrahedra (Fig. 25). The vanarsite-group minerals form from 628 low-temperature aqueous solutions with V and As derived from the oxidation of primary 629 unoxidized phases. 630

Ilmajokite, Na<sub>11</sub>KBaCe<sub>2</sub>Ti<sub>12</sub>Si<sub>37.5</sub>O<sub>94</sub>(OH)<sub>31</sub>29H<sub>2</sub>O, is the third most complex mineral, 631 which was first reported from the hydrothermal vein in Karnasurt Mountain, Lovozero, Kola 632 Peninsula, Russia (Bussen et al. 1972). The mineral easily dehydrates in air, which prevented 633 its structure solution for more than forty-five years. Recently, Zolotarev et al. (2020) were 634 finally able to solve the crystal structure and described it as a multilevel hierarchical 635 framework structure (Fig. 26). The crystal structure is based upon a 3D titanosilicate 636 framework consisting of trigonal prismatic titanosilicate (TPTS) clusters centered by Ce<sup>3+</sup> in 637 [9]-coordination. There are two symmetry-independent clusters within the unit cell (Fig. 27). 638 In each cluster, three [Ti<sub>2</sub>O<sub>10</sub>] dimers of edge-sharing TiO<sub>6</sub> octahedra in parallel orientation 639 form a trigonal prism centered by Ce<sup>3+</sup> cations. The triple-dimer titanate structure is 640 surrounded by SiO<sub>4</sub> tetrahedra to form a TPTS cluster. Four adjacent TPTS clusters are linked 641 into four-membered rings within the (010) plane and linked into ribbons parallel to [101]. The 642 ribbons are organized into layers parallel to (010) and modulated with a modulation 643 wavelength of 32.91 Å and an amplitude of 13.89 Å. The layers are further linked into a the 644 titanosilicate framework via additional SiO<sub>4</sub> tetrahedra. The Na<sup>+</sup>, K<sup>+</sup>, Ba<sup>2+</sup> and H<sub>2</sub>O groups 645 occur in the framework cavities and have different occupancies and coordination 646 environments. As it was mentioned above, the crystal structure of ilmajokite possesses a 647 multilevel hierarchical structure (Fig. 28). The first (lowest) level consists of atoms that are 648 grouped into coordination polyhedra (second level). The TiO<sub>6</sub> octahedra are linked to form 649 dimers (third level). The dimers together with SiO<sub>4</sub> tetrahedra and centering Ce<sup>3+</sup> cations 650 comprise TPTS clusters (fourth level). The clusters are linked to form four-membered rings 651 (fifth level), which are further interlinked to form ribbons (sixth level). The ribbons are united 652 into a three-dimensional octahedral-tetrahedral framework (seventh level), which, together 653 654 with alkali metal,  $Ba^{2+}$  cations and  $H_2O$  molecules complete the structure organization (eighth level). The hierarchical complexity is reflected in the high amount of Shannon information, 655 11990.129 bits per unit cell after H-correction. 656

Paulingite-(Ca) (Lengauer et al. 1997) and fantappieite (Cámara et al. 2010) are two 657 aluminosilicates based upon frameworks consisting of corner-sharing TO<sub>4</sub> tetrahedra (T = Al, 658 Si). Both frameworks can be considered as built up by the linkage of polyhedral cages as 659 described elsewhere (Krivovichev 2013a,b). The two minerals represent good examples 660 illustrating the variety of contributions to the total structural complexity, including the 661 difference between structural and topological complexity, when the latter is estimated as a 662 Shannon information content of the ideal structure with the maximal possible symmetry 663 (Krivovichev, 2018). For instance, the topological complexity parameters for the paulingite 664 framework (PAU) are 1008 atoms per cell, 4.726 bit/atom and 4763.456 bit/cell with the 665 maximal symmetry space group  $Im\overline{3}m$  identical to that of the mineral (Table 1). The addition 666 of interstitial species (Ca<sup>2+</sup> cations and H<sub>2</sub>O molecules) results in the approximately doubling 667 increase of the number of atoms (from 1008 to 1988) and the total information per cell (from 668 4763 to 11591 bits). In the case of fantappieite, the situation is different. The topological 669 symmetry of the framework is  $R\overline{3}$ , which is higher than the space group of the mineral,  $P\overline{3}$ . 670 The topological complexity of the tetrahedral framework per cell is 878.790 bits, but the 671 perfect Al/Si ordering over tetrahedral sites results in the decrease of the symmetry from  $R\overline{3}$  to 672  $P\overline{3}$  (which is the *topochemical* symmetry group for the framework) and the increase of the 673 structural information per cell from ~879 to ~2636 bits (Krivovichev 2013b). The filling of 674

the framework cavities by cations and H<sub>2</sub>O molecules more than doubles the complexity to 675 676 ~6112 bits per cell.

The five most complex mineral structures reflect the basic mechanisms of the 677 generation of crystal-structure complexity of minerals: the formation of nanoscale large 678 polyatomic clusters (usually polyoxometalates (Krivovichev 2020)) and the modular 679 680 architecture, when the structure is based upon a combination of one or several large modules (Krivovichev 2013a). The high hydration states also favor the high Shannon information 681 content, due to the high number of H atoms. 682

683

#### 3.5. Information-density analysis 684

The structural information densities for ewingite, morrisonite and ilmajokite are in the 685 range of 0.488-0.793 bits Å<sup>-3</sup>, which is equivalent to 4.88-7.93 10<sup>23</sup> bits cm<sup>-3</sup>. However, it 686 should be taken into account that the information density is the function of the size of the 687 atoms, and the high hydration states of the three minerals contribute essentially to the  $\rho_{inf}$  high 688 values. For anhydrous minerals, the information density is much lower. The variations of 689 information density versus the ionic size can be illustrated by the example of suanite, 690 Mg<sub>2</sub>B<sub>2</sub>O<sub>5</sub>, and natrosilite, Na<sub>2</sub>Si<sub>2</sub>O<sub>5</sub>, which have the same total structural information content, 691 114.117 bits/cell (Krivovichev 2013a). However, their information densities are drastically 692 different (0.333 and 0.242 bits Å<sup>-3</sup>, respectively), which is an obvious consequence of the 693 different ionic radii of the Mg<sup>2+</sup> and Na<sup>+</sup> ions, on one hand, and of the B<sup>3+</sup> and Si<sup>4+</sup> ions, on the 694 other. 695

It is notable that the structural information density of minerals ( $\sim n \cdot 10^{23}$  bit cm<sup>-3</sup>) is many 696 orders higher than the volumetric densities of information of hard disks and flash memory 697  $(\sim 10^{13} \text{ and } 10^{16} \text{ bit cm}^{-3}, \text{ respectively})$ , and even exceeds those of DNA memory in both liquid 698 and crystalline states ( $\sim 10^{19}$  and  $10^{21}$  bit cm<sup>-3</sup>, respectively) (Zhirnov et al. 2016). However, it 699 should be kept in mind that the Shannon information in crystals is redundant due to their 700 periodic structure, and the original information is restricted to one reduced unit cell only. On 701 the other hand, the estimate of  $\sim n 10^{23}$  bit cm<sup>-3</sup> can be seen as a possible maximum for 702 information storage attainable by the manipulation of matter on the atomic scale, if future 703 technologies would allow to build an aperiodic structure with each atom having a precise 704 705 position relative to its environment. It should also be mentioned that the information density discussed herein and in the section 3.2 relates to the ideal crystalline state and does not take 706 into account other information contained in each mineral crystal such as defects, trace and 707 minor elements, isotopes and other chemical inhomogeneties, etc., which bears on the unique 708 geological and geochemical history of minerals. In order to quantify this information, one has 709 to develop other approaches, perhaps exceeding the limits of the Shannon theory. 710

711

#### **3.6.** Chemical complexity 712

The information-theoretic approach allows for the investigation of relations between 713 structural and chemical complexity. The latter can be defined by analogy with the structural 714 complexity (equations 1-4) as the amount of chemical Shannon information per atom and per 715 formula unit (f.u.). In order to do this, the crystal chemical formulae of minerals should be 716 written in a canonical way in order to determine the minimal set of species-defining 717 constituents (i.e., chemical elements that are dominant in particular sites in a crystal 718

structure). It should be noted that the assignment of an element as species-defining is determined by the rules of the definition of new mineral species given by the International Mineralogical Association (Mandarino et al. 1984; Nickel 1992, 1995). The 'canonical' formulae of minerals are stored in the official IMA list of mineral species continuously updated by Pasero (2020).

The information-based analysis of chemical complexity was first suggested in (Siidra et al. 2014). Following this approach, for the idealized chemical formula of a mineral or inorganic compound,  $E^{(1)}{}_{c1}E^{(2)}{}_{c2}...E^{(k)}{}_{ck}$ , where  $E^{(i)}$  is an *i*th chemical element in the formula and  $c_i$  is its integer coefficient, the chemical information can be calculated as follows:

728

$$\sum_{\substack{\text{chem} I_G = -i=1}}^{k} p \sum_{i=1}^{k} \Box p \qquad (bits/atom) \qquad (5),$$

$$\sum_{\substack{\text{chem} I_{G,total} = e }}^{k} p \sum_{i=1}^{k} p \sum_{i=1}^{k} \Box p \qquad (bits/f.u.) \qquad (6),$$

729

731

where *k* is the number of different elements in the formula and  $p_i$  is the random-choice probability for an atom of the *i*th element, that is:

- 734
- 735 736

 $p_i = c_i / e \tag{7},$ 

737 738

739

k

where *e* is the total number of atoms in the chemical formula:

 $e = \sum_{i=1}^{k} \Box c_i \tag{8}.$ 

740

The average chemical complexity values obtained from the analysis of chemical complexity of all mineral species known today are:  $<^{chem}I_G > = 1.62(2)$  bits/atom and  $<^{chem}I_{G,total} > = 62(6)$  bits/cell. Note that the chemical complexity parameters are smaller than the structural complexity ones. It was shown that the structural and chemical complexities of minerals correlate strongly, though the character of this correlation is different for different measures (Krivovichev et al. 2018).

747 Fedorov (1913, 1914) and Groth (1921) pointed out that, in general, symmetry of crystalline compounds correlates with their chemical complexity. Less complex compounds 748 (e.g., elements) tend on average to have higher symmetries than compounds consisting from 749 two elements, etc. Both Fedorov and Groth pointed out that this empirical observation, also 750 known as a Fedorov-Groth law, has an 'approximate' character only, i.e. is of statistical nature 751 752 that allows exceptions, but works on a global scale. Recently, it was demonstrated that the Fedorov-Groth law is valid and statistically meaningful, when chemical complexity is 753 expressed according to the equation (5) as the amount of Shannon chemical information per 754 atom and the degree of symmetry as the order of the point group of a mineral (Krivovichev, 755 756 Krivovichev 2020).

# 758 **4. Structural complexity, disorder phenomena and the rise of ionic** 759 **properties**

# 760 **4.1 Introduction**

One of the most fascinating aspects related to the complexity of mineral structures is 761 related to the concept of disorder, and, to be more specific, to ionic conduction phenomena 762 related to disorder. Although in an ideal periodic compound there is little space for an atom to 763 diffuse, structural defects due to minor positional disorder (slight deviations from the ideal 764 stacking) commonly exist. What seems an unimportant disorder may be responsible for the 765 existence of different polytypes of the same compound and for the stabilization of different 766 structures as a function of temperature and pressure. From a thermodynamic point of view, at 767 0 Kelvin the atoms of an ideal crystal are arranged in a way to get the lowest free energy. With 768 increasing temperature, the entropic contribution (a measure to quantify the disorder) to the 769 free energy becomes important. As a consequence, there is the occurrence of crystal defects, 770 which can be simply considered the response of the system to reduce the free energy through 771 an increase in the entropy. Crystal defects that play an active role in ion conduction are 772 'Schottky' and 'Frenkel' defect, the so-called 'point defects' in crystals. Thanks to them, ions 773 can be either brought across the solid giving rise to conductivity (vacancy migration) or 774 moving to an interstitial site and then subsequently jump to a neighbouring interstitial site and 775 so on, resulting in long distance motion of the ion (interstitial migration). 776

From the discussion above it is evident that there is a close interplay between the ion motion and the crystal structure where the motion occurs. Indeed, the long-range motions of ions that lead to high conductivity in solids require high density of mobile-ion-sites along with a network of 'smooth' conduction channels connecting them (Padma Kumar and Yashonath 2006). For this reason, a detailed understanding of the structural features is of particular importance in the context of ionic conductors.

Superionic conductors or fast ion conductors have a massive use in diverse technological applications: as electrolytes in batteries used in pace-makers, mobile telephones, laptops, and in electrochemical devices as electrode materials. Interestingly, some of them have been discovered in nature and characterized before their use as synthetic compounds. In other cases, Nature has been of inspiration for new technologically-important materials.

Among the most important materials for solid electrolyte applications there are "NASICONs compounds", NaSbO<sub>3</sub>, known in nature as the mineral brizziite (Olmi and Sabelli 1994), and Ag-Cu sulfosalts (e.g., Bindi and Biagioni 2018). Below, a brief description of the first two compounds together with a more exhaustive essay of Ag-Cu-sulfosalts is reported.

794

# 795 **4.2 NASICON**

The term "NASICON" is applied to the solid with chemical formula  $Na_4Zr_2(SiO_4)_3$ . Actually, it describes a series of compounds with the general formula  $Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$ , where 0 < x < 3. There are a number of chemically and structurally related compounds to NASICONs, including langbeinite,  $K_2Mg_2(SO_4)_3$  (Mereiter 1979), a very well-known mineral for its technological importance (Krivovichev 2009). The structure of NASICON is based upon the octahedral-tetrahedral framework shown in Fig. 29. Each octahedron shares vertices with six adjacent tetrahedra and each tetrahedron shares vertices with four adjacent octahedra.

### **4.3 NaSbO<sub>3</sub>, brizziite**

The structure of brizziite is similar to those of the ilmenite group minerals and consists of gibbsite-type octahedral sheets, perpendicular to the c axis (Fig. 30). The bond distances of the Na-polyhedron are in the range 2.25-2.78 Å, whereas the Sb-octahedron exhibits a mean bond distance of 1.989 Å. Each Na and Sb octahedron shares edges with three symmetryrelated octahedra to form Na and Sb layers, respectively. Each octahedron also shares a face with another octahedron of an adjacent layer, but the opposite face is unshared. Thus, pairs of Na and Sb octahedra alternate with octahedral holes along the c axis. There are six alternating Na and Sb sheets in the unit cell, to form a hexagonal close-packed framework. Such a structure is responsible for the high ionic conductivity measured (Wang et al. 1994).

814

### 815 4.4 Ag- and Cu-bearing sulfosalts

Most of Ag- and Cu-bearing sulfosalts represent an outstanding example of complex 816 structures associated with ionic conduction. Their structural complexity is mainly due to the 817 difficulty in accurately describing the  $Ag^+$  or  $Cu^+$  electron density. Indeed, both  $Ag^+$  or  $Cu^+ d^{10}$ 818 elements easily adopt various complex asymmetric coordinations due to an s/d orbital mixing 819 and/or polarization factors (Gaudin et al. 2001 and references therein). Therefore, both these 820 ions can be found in different, but very close sites, which favour the presence of strong ionic 821 conductivity. As described above, the ease to deform the electron density lowers the activation 822 energy of the site-to-site jumps giving rise to some disorder in the crystal structure. In fast 823 ionic conductors, an ionic species can move easily, giving a liquid-like structure in an open 824 framework (tunnels, layers, etc.). 825

826

### 827 4.4.1 Pearceite, polybasite and fettelite

828 The pearceite-polybasite minerals have been known for a long time and were divided by Frondel (1963) into two series: the first one, formed by pearceite (Ag,Cu)<sub>16</sub>(As,Sb)<sub>2</sub>S<sub>11</sub> and 829 antimonpearceite (Ag,Cu)<sub>16</sub>(Sb,As)<sub>2</sub>S<sub>11</sub>, characterized by a "small" unit cell [labeled 111] and 830 high Cu content, and the second one, formed by polybasite (Ag,Cu)<sub>16</sub>(Sb,As)<sub>2</sub>S<sub>11</sub> and 831 arsenpolybasite (Ag,Cu)<sub>16</sub>(As,Sb)<sub>2</sub>S<sub>11</sub>, with double unit-cell parameters [labeled 222] and low 832 Cu content. Moreover, the existence of an intermediate type of unit cell labeled 221 was 833 claimed for both polybasite (Harris et al. 1965; Edenharter et al. 1971) and arsenpolybasite 834 (Minčeva-Stefanova et al. 1979). From the crystallographic point of view these minerals were 835 initially reported as monoclinic C2/m, although dimensionally pseudo-hexagonal (Peacock 836 and Berry 1947; Frondel 1963; Harris et al. 1965; Hall 1967; Sugaki et al. 1983). Bindi et al. 837 (2006a) solved and refined the crystal structure of pearceite in a space group of type P3m1838 (Fig. 31). They showed that the pearceite structure can be described as a regular alternation of 839 two module layers stacked along the c axis: a first module layer (labeled A), with general 840 composition  $[(Ag,Cu)_6(As,Sb)_2S_7]^2$ , and a second module layer (labeled B), with general 841 composition  $[Ag_9CuS_4]^{2+}$ . The fast ion conductivity occurs in the latter module layer (Fig. 32). 842 Although no long-range ordering at low temperature could be established for pearceite, this 843 ordering was shown in different samples of polybasite by Evain et al. (2006), who evidenced 844 complex polytypism phenomena (i.e., 221 and 222 unit-cell types). 845

These authors solved and refined the crystal structure of both polybasite-221 (spacegroup type  $P\overline{3}21$ ; Fig. 33) and polybasite-222 (space-group type C2/c; Fig. 34) and proposed a possible mechanism regulating the ordering in these minerals.

The crystal structures of the remaining members of the group (i.e., antimonpearceite, arsenpolybasite-221 and -222) were studied at room temperature by Bindi *et al.* (2006b). These authors showed that antimonpearceite possesses the same structural arrangement observed for pearceite and that the polytypism phenomena occurring in different arsenpolybasites (i.e., 221 and 222 unit-cell types) show strong analogies with those observed

in polybasites. The complexity of these minerals can be evidenced by the number of unit-cell 854 types used to describe all the members of the group (Fig. 35). 855

It was then clear that all the members of the pearceite-polybasite group present the same 856 high-temperature structure and that it is observed at room temperature either in their high 857 temperature (HT) fast ion conductivity form (pearceite) or in one of the low temperature (LT) 858 fully ordered (222), partially ordered (221) or still disordered (111) forms, with transition 859 temperatures slightly above or below room temperature. A detailed investigation of the phase 860 transitions, by means of conductivity and calorimetric studies and *in situ* single-crystal X-ray 861 diffraction experiments, was carried out by Bindi et al. (2006b). 862

Following the determination of the crystal structures for all the members of this group 863 and the elucidation of the conducting mechanism, these minerals were considered as a family 864 of polytypes. Indeed, the solution of the crystal structure allowed also the understanding of 865 the doubling of the unit-cell parameters, that is related to the Ag ordering. In agreement with 866 this deeper knowledge, a revision of the nomenclature was proposed by Bindi et al. (2007). 867 The old names antimonpearceite and arsenpolybasite were discredited, whereas the names 868 pearceite and polybasite, previously defined on structural basis (i.e., 111 and 222, 869 respectively), were redefined on chemical basis, with As > Sb for the former and Sb > As for 870 the latter. 871

If silver is the main driving force responsible for the fast ionic conductivity, copper 872 seems to play an important role in the disorder of particular portions of the structure. Bindi et 873 al. (2007) showed that not all the 111 aristotype structures give a long range ordered low-874 temperature structure. There are indeed Cu-poor pearceite-polybasite minerals that remain 875 trigonal with the 111 cell and  $P\overline{3}m1$  space-group type, and intermediate pearceite-polybasite 876 minerals with the 221 cell and P321 space-group type. This particularity is to be related to the 877 disorder occurring, whatever the temperature, within the  $[(Ag,Cu)_6(As,Sb)_2S_7]^{2-}$  A module 878 layer. Indeed, with the lowest (1.54, 1.29, 1.08) and the highest (4.5) Cu content, Bindi et al. 879 (2006b) obtained two different fully ordered structures. As the Cu content increases (2.29, 880 1.69, and 1.55) from the lowest values, 221 compounds with only a partial ordering were 881 observed. For a further increase of the Cu content (3.8) the structure remained disordered (111 882 cell), whatever the temperature. 883

In conclusions, the pearceite-polybasite group of minerals can be considered as a series 884 with the same aristotype, fast ion conducting form at high temperature. Depending upon the 885 Cu content, an ordering occurs with transition temperatures related to that content: the lower 886 the Cu content, the higher the transition temperature from the fast ion conducting HT form to 887 the non ion conducting form. 888

Another interesting mineral structure, which shows similarities with those of the 889 pearceite-polybasite minerals, is that of fettelite, [Ag<sub>6</sub>As<sub>2</sub>S<sub>7</sub>][Ag<sub>10</sub>HgAs<sub>2</sub>S<sub>8</sub>]. The crystal 890 structure of fettelite (Bindi et al. 2009a) consists of an alternation of two kinds of layers along 891 the c-axis: layer A with general composition  $[Ag_6As_2S_7]^{2-}$  and layer B with general 892 composition  $[Ag_{10}HgAs_2S_8]^{2+}$  (Fig. 36). In this structure, the Ag atoms adopt different 893 coordinations, extending from quasi linear to quasi tetrahedral, the AsS<sub>3</sub> groups form trigonal 894 pyramids as are typically observed in sulfosalts, and Hg links two sulfur atoms in a linear 895 coordination. By means of an integrated high-temperature single-crystal X-ray diffraction 896 (HT-SCXRD), differential scanning calorimetry (DSC), and complex impedance spectroscopy 897 (CIS) study, Bindi and Menchetti (2011) showed that fettelite exhibits a ionic-transition at 898 about 380K toward a disordered phase having a trigonal symmetry with the *a* and *b* unit-cell 899

parameters halved. In the HT-structure, what induces the disorder in the B layer are both Ag 900 901 and Hg cations, which are found in various sites corresponding to the most pronounced probability density function locations of diffusion-like paths (Fig. 37). So, even if Hg is a 902 minor element in fettelite, it does play a very important role in the stabilization of the 903 disorder. The study by Bindi and Menchetti (2011) indicated that at least two polytypes could 904 905 exist for fettelite, the ordered, monoclinic RT-structure (space-group type C2), and a fast ion conducting, trigonal, disordered HT-form (space-group type  $P\overline{3}m1$ ) with a and b parameters 906 halved. 907

908

### 909 4.4.2 Argyrodite-canfieldite series

The minerals of the argyrodite group mainly consist of three members: argyrodite 910 Ag<sub>8</sub>GeS<sub>6</sub>, canfieldite Ag<sub>8</sub>SnS<sub>6</sub>, and putzite (Cu<sub>4.7</sub>Ag<sub>3.3</sub>)GeS<sub>6</sub>. According to Wang (1978), 911 argyrodite and canfieldite are isostructural (space-group type Pna2<sub>1</sub> or Pnam), and a solid 912 solution exists between these two minerals. The crystal structure of argyrodite was published 913 by Eulenberger (1977) and that of a tellurian variant of canfieldite was reported by Bindi et al. 914 (2012a). Several structural studies on synthetic argyrodite-type compounds have been 915 reported, mainly because such phases are of interest for their manifold structural and physical 916 properties, for example, as electrolytes (e.g., Evain et al. 1998; Gaudin et al. 2001; Rao and 917 Adams 2011). These compounds undergo three phase transitions: the high-temperature, ionic-918 conducting phase crystallizes in the space-group type  $F\overline{4}3m$  (Fig. 38). The medium-919 920 temperature phase has space-group type  $P2_13$ , and, finally, the low-temperature phase has an apparent space-group type  $F\overline{4}3m$ , but it actually adopts an orthorhombic symmetry (space-921 group type:  $Pna2_1$ , Pnam or  $Pmn2_1$ ). 922

Recently Bindi et al. (2017a) reported a heretofore unobserved compound belonging to 923 the argyrodite group, named spryite, exhibiting the ideal formula  $Ag_8(As^{3+}_{0.5}As^{5+}_{0.5})S_6$ , which 924 represents the first As<sup>3+</sup>-bearing member of the argyrodite group (Fig. 39). It was found in the 925 Ag- and Mn-rich zone of the Uchucchacua polymetallic deposit, Oyon district, Catajambo, 926 927 Lima Department, Peru, a complex vein-type deposit related to a dacitic intrusion cutting 928 through Cretaceous and Tertiary formations on the West side of the Occidental Cordillera of 929 Central Andes (Oudin et al. 1982). From a structural point of view, spryite is intimately twinned with six twin domains. The most peculiar feature is that arsenic is present in both 930 trivalent and pentavalent state.  $As^{3+}$  forms  $AsS_3$  pyramids typical of sulfosalts, (Ge<sup>4+</sup>, As<sup>5+</sup>) 931 links four S atoms in a tetrahedral coordination, and Ag occupies sites with coordination 932 ranging from quasi linear to almost tetrahedral connected into a framework (Fig. 40). 933

Noteworthy, a network of non-interacting Ag cations is established for spryite. This 934 behavior is different with respect to that usually reported for argyrodite-like compounds 935 (Belin et al. 2001), which show a strong disorder in the sub-lattice of the moving cations at 936 room temperature. In this light, spryite represents the first argyrodite-type compound which 937 does not behave as a fast ionic conductor. Likely, the presence of  $As^{3+}$  inhibits the typical 938 ionic conductivity observed in these compounds. The presence of partially occupied  $As^{3+}S_{3-}$ 939 pyramids could indeed hinder the formation of the 'quasi-liquid like' structure of the mobile 940 ions which usually are highly delocalized over the sites available to them. The free energy 941

- associated with the regular sites in spryite is likely higher than that of the interstitial sites, thus 942 making the conduction mechanism highly unfavorable. 943
- 944

#### 5. Structural complexity in sulfosalts and the role of minor constituents 945 **5.1 Introduction** 946

Sulfosalts are an informal group of chalcogenides (Moëlo et al. 2008), often 947 characterized by very complex crystal structures. Dittrich et al. (2009) reviewed some 948 interesting properties and applications of these minerals. For instance, due to the strong 949 anisotropy of the crystal structures of several sulfosalts, the crystal growth velocities can be 950 severely anisotropic, giving rise to individuals characterized by aspect ratios of more than 951 952 1000, with potential application in nanotechnology (Fig. 41). Other interesting applications are in photovoltaics, thermoelectrics, phase change memory, X-ray detectors, and so on. 953

954 Sulfosalt crystal structures are sometimes very complex, with large numbers of 955 independent atomic positions and large unit-cell volumes. Actually, these crystal structures can be broken up into relatively simpler fragments ("modules"; see Section 2.2) that are 956 recombined through the action of structure-building operators. Among sulfosalts, a large 957 group is represented by the so-called rod-based sulfosalts. They are represented by Pb/Sb and 958 Pb/Bi sulfosalts whose building principles were worked out by Makovicky (1993, 1997). 959 Their crystal structures can be described as formed by cut outs of basic structures like 960 PbS(NaCl) or SnS; these building units (rods) have generally a lozenge cross-section, are 961 several PbS/SnS subcells wide and two or more atomic layers thick. These building units are 962 then connected and stacked to give rise to three-dimensional structures. Usually, these phases 963 show a distinct partitioning of Sb and Bi within rod interiors, where lone-electron-pair 964 micelles are formed, and of Pb on the rod surfaces. Mixed Pb/(Sb,Bi) positions in the rod 965 interiors can occur, in order to maintain charge balance and minimizing structural distortion. 966 Makovicky (1993) proposed three fundamental categories of rod-based structures, i.e., (i) the 967 968 layer-, (ii) the chess-board, and (iii) the cyclic category (Fig. 42). The next step in structural complexity was represented by the so-called boxwork structures. 969

970 971

# 5.2 Boxwork structures

972 Boxwork structures are the currently known most complex modular category of sulfosalts. This term was first introduced by Makovicky et al. (2001) during the description of 973 nevite, a silver-copper sulfobismuthite with formula Ag<sub>2</sub>Cu<sub>6</sub>Pb<sub>25</sub>Bi<sub>26</sub>S<sub>68</sub>. Meanwhile, a series 974 of Pb/Sb oxy-sulfosalts and oxy-chloro-sulfosalts were described by a French-Italian research 975 976 group of the Nantes and Pisa Universities, showing the same kind of very complex crystal structures (Table 2). These latter authors defined the occurrence of three different kinds of 977 rods, namely rods A, B, and C1-C2 (Moëlo et al. 2000; Palvadeau et al. 2004). Makovicky and 978 979 Topa (2009) gave a formal definition and a description of the architecture of these complex sulfosalts. A boxwork structure (Fig. 43) can be described as formed by three structural 980 elements: 981

i) walls (= rods  $C_1$ - $C_2$ ), based on double layers of SnS or more rarely PbS archetype (see 982 Section 2.1). Walls are sinuous and start on one side of the wall and end on the other side. It is 983 worth noting that such a sinuosity can be obtained through the insertion of peculiar structural 984 features, e.g., kermesite-like fragments like in scainiite (Moëlo et al. 2000) or an Hg-centered 985 octahedron as in marrucciite (Orlandi et al. 2007). 986

ii) partitions (= rods A), usually represented by four-atomic-layers-thick lozenge-shaped 987 rods based on the SnS archetype. Only in marrucciite, partitions based on PbS archetype have 988 been observed. In nevite, the partitions are only two-atomic-layer-thick. The width varies 989 between two and four polyhedra. 990

991 iii) *fill elements* (= rods B) are rods of SnS archetype and, less frequently, Pb archetype. 992 The fill element composition varies between  $MS_4$  (where M is a cation) (e.g, in vurroite – 993 Pinto *et al.* 2008) and  $M_{18}S_{26}$  for chovanite (Makovicky and Topa 2009; Biagioni and Moëlo 994 2017).

It is worth noting that such a structural complexity seems to be closely related to the 995 occurrence of minor constituents. In particular, Makovicky and Topa (2009) highlighted the 996 role played by oxygen in generating the so-called "kermesite-like configuration", as first 997 defined by Moëlo et al. (2000). Indeed, Makovicky (1993) showed that only a limited number 998 of rod shapes and sizes can be combined forming rod-layer sulfosalts and chessboard-type 999 sulfosalts. The existence of additional new sulfosalts, containing in particular antimony, can 1000 be related to the occurrence of this structural feature, similar to that described in the oxy-1001 sulfide kermesite, Sb<sub>2</sub>S<sub>2</sub>O (e.g., Bonazzi et al. 1987), and acting as a structure modifier, 1002 favouring the fitting of the structural modules. Kermesite-like configurations observed in 1003 scainiite and other lead-antimony oxy-sulfosalts are shown in Figure 44. The most common 1004 configuration is represented by the alternation, along the rod extension, of an oxygen atom 1005 and a vacancy. Usually, taking into account the strongest bonds for Sb<sup>3+</sup> and As<sup>3+</sup> (i.e., those 1006 having Me-S distance shorter than 2.70 Å), a trigonal pyramidal coordination is typically 1007 observed, satisfying the bond-valence requirements. In the kermesite-like configurations, only 1008 1009 two short Me-S distances are present, and the third bond is represented by Me-O bond, with the oxygen atom above or below Sb/As. Clearly, the crystallization of such complex structures 1010 1011 is strictly related to peculiar  $f(O_2)/f(S_2)$  conditions (e.g., Orlandi *et al.* 1999).

1012 Vurroite and its isotype tazieffite are two other sulfosalts showing a boxwork structure, stabilized by Sn and Cl and Cd and Cl as minor chemical constituents, respectively (Fig. 45). 1013 Actually, these minerals can be really considered a masterpiece of structural complexity, 1014 showing a very complex crystal structure, an order-disorder<sup>4</sup> (OD) character, and the 1015 occurrence of a widespread polysynthetic twinning. The two latter features (OD nature and 1016 twinning) are intimately related. On the basis of the characteristic shown by X-ray diffraction 1017 patterns, Pinto et al. (2008) derived the possible polytypes of vurroite and demonstrated their 1018 occurrence in the studied material. The extensive polysynthetic twinning shown by vurroite is 1019 related to the OD nature of this mineral. Following the solution of the crystal structure of 1020 vurroite, Zelenski et al. (2009) reported the structural features of isotypic tazieffite. 1021

1022 The role of minor elements (both cations and anions) in stabilizing complex compounds is exemplified by several sulfosalts having a boxwork structure. For instance, Sn and Cl 1023 favours the crystallization of vurroite (Garavelli et al. 2005), whereas Cu, Hg, and O are 1024 1025 pivotal for the crystallization of rouxelite (Orlandi et al. 2005). In this latter mineral, distorted  $HgS_{2+4}$  octahedra occur in the walls; this distortion, related to the tendency of  $Hg^{2+}$  to form 1026 two linear short bonds, favours the insertion of CuS<sub>4</sub> tetrahedra in the crystal structure, 1027 1028 adjacent to the walls. In this way, Hg acts as a structure modifier. In addition, in the crystal structure of rouxelite, portions with Sb atoms showing the kermesite-like configuration occur. 1029

1030 1031

### 5.3 Other zinkenite-related complex sulfosalts

1032 The description of these complex crystal structures using the modular approach 1033 developed by Makovicky (1993, 1997) can neglect some strong bonds. Since the first 1034 description of lead-antimony sulfosalts by the Nantes-Pisa research group (e.g., Moëlo *et al.* 1035 2000), another type of layer definition was proposed, taking into account the distribution of 1036 strong and weak bonds. In this alternative (and in some ways complementary) approach,

 $<sup>^{4}</sup>$  Order-disorder structures are formed by one or more kind of layers (not necessarily structural layers) stacked

according to two or more geometrically equivalent ways (Ferraris *et al.* 2008 and references therein). An infinite
 number of different layer sequences are possible, both ordered and disordered. Ordered sequences are known as

<sup>63</sup> polytypes, corresponding to Maximum Degree of Order (MDO) sequences.

complex rod layers are defined, their boundaries passing through lone-electron-pair micelles 1037 and through interfaces between archetype rods. This description highlights the organization of 1038 crystal structures around pseudotrigonal columns (see for instance the crystal structure of 1039 chovanite in Figure 43) usually organized around a Pb<sub>6</sub>S<sub>12</sub> triangular core. 1040

This latter structural motif, typical of zinkenite, Pb<sub>9</sub>Sb<sub>22</sub>S<sub>42</sub> (Biagioni et al. 2018), occurs 1041 1042 also in other related phases having crystal structures not belonging to the boxwork group but to the chess-board type. However, their structural complexity is still very relevant. Moëlo et 1043 al. (2012) reported the crystal structure of two complex Ag-Pb sulfosalts, sterryite and 1044 1045 parasterryite, Cu(Ag,Cu)<sub>3</sub>Pb<sub>19</sub>(Sb,As)<sub>22</sub>(As<sub>2</sub>)S<sub>56</sub> and Ag<sub>4</sub>Pb<sub>20</sub>(Sb,As)<sub>24</sub>S<sub>58</sub>, respectively. These two minerals, along with ciriottiite, Cu(Cu,Ag)<sub>3</sub>Pb<sub>19</sub>(Sb,As)<sub>22</sub>(As<sub>2</sub>)S<sub>56</sub> (Bindi et al. 2016a), are 1046 expanded derivative of owyheeite, Ag<sub>3</sub>Pb<sub>10</sub>Sb<sub>11</sub>S<sub>28</sub> (Moëlo et al. 1984; Laufek et al. 2007), a 1047 rare Ag-Pb sulfosalt showing an OD nature (Makovicky and Olsen 2015). Figure 46 shows 1048 1049 some structural features of sterryite and parasterryite. Moëlo et al. (2012) defined complex columns representing the fundamental building blocks of these compounds, principally 1050 considering the surfaces of weakest bonding. In this way, a triangular prismatic core can be 1051 1052 distinguished; around this core, two arms of unequal length, indicated as "long" and "short", are organized. It is worth noting that sterryite and parasterryite have the same triangular 1053 prismatic core, a very similar long arm, and a (Sb,As)<sub>2</sub>S<sub>4</sub> group at the basis of the short arm. 1054 1055 The similarity index between these two structures, defined as the ratio between the common positions and the total atoms in the formula unit, is close to 90%, being 94/103 in sterryite (94 1056 being the common positions and 103 the total number of atoms) and 94/106 in parasterryite. 1057 1058 The difference between these two complex minerals occurs at the end of the short arm (Fig. 46). In particular, sterryite (Fig. 46a) shows a partially occupied Cu site and an As-As pair 1059 (Fig. 46b and c), with As–As distance of 2.63 Å, comparable with those observed in realgar 1060 1061 As<sub>4</sub>S<sub>4</sub> (2.566 Å – Mullen and Nowacki 1972) and in wakabayashilite (2.656 Å – Bonazzi et al. 2005). In parasterryite, the short arm is Ag-rich, with four Ag sites (Fig. 46d and e). It is 1062 interesting to observe that this chemical difference of two small structural fragments 1063 connected to topologically identical complex columns has a relevant consequence on the 1064 general organization of the crystal structures of sterryite and parasterryite, resulting in two 1065 different choices corresponding to the  $P2_1/n$  and  $P2_1/c$  settings of the space group, 1066 1067 respectively.

1068 Still more complex is the crystal structure of meerschautite, Ag<sub>5.5</sub>Pb<sub>42.4</sub>Sb<sub>45.1</sub>S<sub>112</sub>O<sub>0.8</sub>, based on two different complex columns (Biagioni et al. 2016). This mineral differs from 1069 sterryite and parasterryite for the space group symmetry,  $P2_1$ , and for the configuration of the 1070 1071 short arms connecting successive pseudotrigonal columns (Fig. 47). One of these arms is Agrich (Fig. 47a and b), whereas the other displays localized Sb-O-Sb bonds, in a kermesite-1072 like configuration (Fig. 47c and d). Meerschautite is the lead-antimony sulfosalt with the 1073 1074 largest unit-cell content (more than 200 atom positions) showing only one O specific position (Biagioni et al. 2016). A mineral that is likely structurally related to sterryite, parasterryite, 1075 and meerschautite is tubulite, Ag<sub>2</sub>Pb<sub>22</sub>Sb<sub>20</sub>S<sub>53</sub> (Moëlo et al. 2013). What is interesting is the 1076 tubular morphology characterizing several samples of this mineral, like those shown in Fig. 1077 41 for robinsonite. The origin of this unusual morphology is probably due to extrinsic factors, 1078 related to the crystallization environment and likely acting on extremely thin lath-like 1079 1080 individuals at the early stages of crystal growth.

1081 1082

### 5.4 Information-based complexity in sulfosalts

A quantitative estimation of the structural complexity of these sulfosalts can be 1083 achieved using the method recently proposed by Krivovichev (2013a) and based on the 1084 information contents of their crystal structures. Table 3 gives the information-based 1085 complexity parameters for the sulfosalts here discussed. 1086

Sulfosalts having a boxwork structure have usually structural information complexities 1087  ${}^{\rm str}I_{\rm G,total}$  in the range 500 – 1000 bits/cell, thus being classifiable as "complex", according to 1088 Krivovichev (2013a). Two of them, marrucciite and pillaite, could seem to be not so complex, 1089 having  ${}^{\text{str}}I_{\text{G,total}}$  of ~450 and 480 bits/cell, respectively, corresponding to an intermediate 1090 complexity. Actually, this apparently relatively low complexity is due to the fact that the 1091 calculations given in Table 3 have been usually performed on the 4 Å sub-structure of 1092 boxwork structures. The superstructure reflections doubling the 4 Å periodicity are usually 1093 very weak and in several cases it was not possible to refine the actual 8 Å structure. This point 1094 1095 is particularly important, as exemplified by chovanite, the mineral showing the largest infill elements currently known (Makovicky and Topa 2009; Biagioni and Moëlo 2017). Indeed, the 1096  $^{\text{str}}I_{G,\text{total}}$  of the 4 Å sub-structure is ~ 800 bits/cell, and consequently this mineral could be 1097 considered as "complex". However, when the real 8 Å structure is taken into account, a 1098 definitely higher  ${}^{str}I_{G,total}$  value is obtained, 3753 bits/cell, agreeing with the very complex 1099 nature of this compound. Similarly, the chess-board structures of sterryite, parasterryite, and 1100 meerschautite, with  ${}^{str}I_{G,total}$  in the range 2800 - 3200 bits/cell, can be considered "very 1101 complex". It is interesting to observe that the pair vurroite/tazieffite, whose studies faced up 1102 to a series of complicated crystallographic issues, has a  ${}^{str}I_{G,total}$  value lower than those shown 1103 by other phases. Indeed, the structural information complexity index <sup>str</sup>I<sub>G,total</sub> takes into account 1104 only the amount of information contained in a mineral species, whereas it neglects other 1105 factors like OD phenomena, twinning, and modulation, which represent a different kind of 1106 1107 complexity that, in some cases, may preclude the full understanding of the actual structural 1108 information hosted within a crystal structure.

1109 1110

### 5.5 Role of minor constituents

1111 Sulfosalts characterized by boxwork structures and other very complex Ag-Pb sulfosalts 1112 (e.g., sterryite, parasterryite, and meerschautite) reveal that in the crystallization of such very 1113 complicated phases a key role is played by minor components, both cations and anions. The 1114 crystal structure solution and refinement of these minerals increase our understanding of the 1115 role of minor constituents, with potential implications in the synthesis of peculiar 1116 technological compounds.

Minor constituents could also give rise to incommensurate structures. In the sulfosalt 1117 1118 realm, a simple example is represented by meneghinite, CuPb<sub>13</sub>Sb<sub>7</sub>S<sub>24</sub> (Fig. 48). Euler and Hellner (1960) and Hicks and Nuffield (1978) interpreted additional weak reflections in the 1119 single-crystal X-ray diffraction patterns as due to a commensurate superstructure. Recently, 1120 Bindi et al. (2017b), using a sample from the Bottino mine (Tuscany, Italy), where this 1121 mineral was originally described in the XIX Century, clearly observed a small (but detectable) 1122 departure of the position of the additional reflections, apparently doubling a 4 Å periodicity, 1123 from the commensurate value 0.5. The crystal structure of meneghinite has been consequently 1124 solved and refined as an incommensurate structure in a four-dimensional superspace (see 1125 Section 6.2), describing the modulation of occupancy of Cu, Pb, and Sb atoms, related to the 1126 substitution mechanism  $Cu^+ + Pb^{2+} = \Box + Sb^{3+}$ . The small departure from the commensurate 1127 structure suggests that other commensurate superstructures observed in complex sulfosalts 1128 could be due, in some cases, to some kinds of incommensurate chemical modulation. 1129

1130 Indeed, until now, classical examples of incommensurability in sulfosalts are 1131 represented by members of the cylindrite homologous series (e.g., Makovicky and Hyde 1132 1992). This is a peculiar kind of incommensurability related to the occurrence of a 1133 pseudotetragonal Q layer, two to four atoms thick and with a PbS archetype, and a 1134 pseudohexagonal H layer of CdI<sub>2</sub>-type or NbS<sub>2</sub>/TaS<sub>2</sub>-type. The misfit between these two kinds 1135 of layers is at the origin of the incommensurate nature of this group of minerals. A recent and 1136 spectacular example is merelaniite, Mo<sub>4</sub>Pb<sub>4</sub>VSbS<sub>15</sub> (Jaszczak *et al.* 2016 – Fig. 49). The 1137 tubular morphology of these minerals is due to intrinsic factors. Indeed, the nucleation of 1138 crystals of cylindrite homologues starting from a pair of Q and H layers can induce a 1139 curvature of the constitutive layers, resulting in a macroscopic cylindrical crystal.

1140 Incommensurate modulated and composite structures are a peculiar kind of aperiodic 1141 structures, as will be discussed in the next chapter.

1142

# 1143 **6. Aperiodic minerals**

### 1144 **6.1 Introduction**

Aperiodicity in minerals refer to the aperiodic nature of their crystal structures. Since 1145 the 1970s, we have learned that crystal structures do not necessarily obey the classical concept 1146 of three-dimensional periodicity of their atomic arrangements. First, incommensurately 1147 modulated structures were observed, followed by another family of structures called 1148 composites and finally, quasicrystals were discovered. These three types of complex 1149 structures are currently referred by the generic term of *aperiodic structures*. They all share in 1150 common the property that their diffraction patterns are essentially discrete but cannot be fully 1151 indexed with the usual triplets of *hkl* integers as is the case for the classical model of crystals. 1152 The discrete nature of diffraction pattern is a consequence of the long-range order of the 1153 corresponding crystal structures but the fact that three integers do not suffice any more is a 1154 consequence of a new type of order which will be presented in this section. 1155

1156 It is interesting to note here the important role played by the study of mineral structures 1157 to the historical development of the concept of aperiodicity in crystals. Mineral structures of 1158 *calaverites*, *natrites* or *labradorites* for example were fundamental for the theoretical 1159 development of aperiodicity (see below).

Before describing a few interesting aperiodic mineral structures, a brief description of the basic concepts used to characterize them will be presented. For a deeper understanding of the subject, the interested reader may refer to the dedicated literature (e.g., van Smaalen 2012, Janssen et al. 2018).

Due to space limitations, examples of the third category of aperiodic minerals, namely 1164 composites, will not be presented here. Their structures have been shortly presented in Section 1165 5.5 and appear essentially in two different families, layered and columnar. In the first case, 1166 two or more layers with their own periodicities are stacked periodically in the third 1167 dimension. In the second case, different columns with their own periodicities form two 1168 dimensional periodic arrays. The world of natural minerals is also very rich in 1169 incommensurate examples of composites. The interested users may consult the pioneering 1170 works of Makovicky and Hyde (1981, 1992) to discover additional interesting examples of 1171 aperiodic minerals. 1172

1173 1174

### 6.2 Short theoretical presentation

1175 Any conventional crystal structure can be described by the individual positions of each 1176 atom contained in its unit cell characterised by the three lattice vectors  $\mathbf{a}_1$ ,  $\mathbf{a}_2$ ,  $\mathbf{a}_3$  and the three 1177 angles  $\alpha_1$ ,  $\alpha_2$ ,  $\alpha_3$ . The determination of the lattice constants is usually performed by diffraction 1178 methods (X-rays, neutron, electron) and therefore it is convenient to introduce the reciprocal 1179 lattice vectors  $\mathbf{a}_i^*$  where the scalar product satisfies the conditions

1180

$$\mathbf{a}_i \cdot \mathbf{a}_j^* = \delta_{ij} \tag{1}$$

1181

1182 Here  $\delta_{ij}$  is the Kronecker symbol, which is 1 if i=j and 0 if  $i\neq j$ .

1183 Diffraction patterns of classical crystals are usually analysed in terms of the reciprocal 1184 lattice vectors with basis  $\mathbf{a}_1^*$ ,  $\mathbf{a}_2^*$  and  $\mathbf{a}_3^*$  by assigning each discrete diffracted intensity to a

1185 reciprocal lattice node which is uniquely characterised by the three integers *hkl* mentioned 1186 before. Once the full set of diffracted intensities is measured, it is in principle straightforward 1187 to obtain the positions of each atom contained in the unit cell.

1188 Let us analyse the following reciprocal lattice layer of diffracted intensities of the 1189 mineral natrite (Dušek et al. 2003; Arakcheeva and Chapuis 2005; Arakcheeva et al. 2010) 1190 illustrated in Figure 50.

1191 It is obvious in this layer that the full set of reflections cannot be characterized in terms 1192 of only two indices h and l. The additional reflections lay on parallel lines and are 1193 equidistantly distributed on both side of each node h2l. It is convenient to define an additional 1194 vector **q** expressed in terms of the reciprocal vectors  $\mathbf{a}_i$ :

1195

$$\mathbf{q} = \alpha_1 \mathbf{a}_1^* + \alpha_2 \mathbf{a}_2^* + \alpha_3 \mathbf{a}_3^* \tag{2}$$

1196 In the specific case, two coefficients  $\alpha_1$  and  $\alpha_3$ , are irrational and  $\alpha_2 = 0$ . In the general 1197 case, we can define a set **H** of lattice vectors to describe the full set of diffraction reflections: 1198

$$\mathbf{H} = h_1 \mathbf{a}_1^* + h_2 \mathbf{a}_2^* + h_3 \mathbf{a}_3^* + m\mathbf{q}$$
(3)

1199 Here the integer coefficients  $h_i$  instead of the equivalent triplet *hkl* are used. If the 1200 integer m = 0, **H** describes a *main* reflection whereas if  $m \neq 0$ , **H** describes a *satellite* reflection. 1201 We are thus faced with the necessity to increase the number of vectors in reciprocal 1202 space and consequently its dimensionality in order to characterize the full set of reflections. 1203 This can be done according to the following embedding given in Figure 51.

1204 The new space embedding to describe the full set of reciprocal vectors is called 1205 superspace and in our particular case, we introduce the four new basis vectors  $\mathbf{a}_{S1}^*,...,\mathbf{a}_{S4}^*$ 1206 expressed in terms of their external and internal components. Once the reciprocal vectors are 1207 defined, we can use the orthogonality relation to obtain the corresponding direct space basis 1208 vectors given in the next relation.

1209

$$\begin{vmatrix} \mathbf{a}_{S1}^{*} &= (\mathbf{a}_{1}^{*}, 0) \\ \mathbf{a}_{S2}^{*} &= (\mathbf{a}_{2}^{*}, 0) \\ \mathbf{a}_{S3}^{*} &= (\mathbf{a}_{3}^{*}, 0) \\ \mathbf{a}_{S4}^{*} &= (\mathbf{q}, 1) \end{vmatrix} \rightarrow \mathbf{a}_{Si} \cdot \mathbf{a}_{Sj}^{*} = \delta_{ij} \rightarrow \begin{cases} \mathbf{a}_{S1} &= (\mathbf{a}_{1}, -\mathbf{q} \cdot \mathbf{a}_{1}) \\ \mathbf{a}_{S2} &= (\mathbf{a}_{2}, -\mathbf{q} \cdot \mathbf{a}_{2}) \\ \mathbf{a}_{S3} &= (\mathbf{a}_{3}, -\mathbf{q} \cdot \mathbf{a}_{3}) \\ \mathbf{a}_{S4} &= (\mathbf{0}, 1) \end{cases}$$
(4)

1210

1211 The next challenge is to find a suitable embedding of the three-dimensional structure 1212 into superspace and a way to reinterpret crystal structures in this new reference frame.

The origin of the satellite reflections observed on diffraction patterns was already known long before the 1970s. However, Korekawa (1967) was the first to present some theoretical backgrounds explaining the origin of the satellite reflections in "labradorite" and other minerals. Their structures were interpreted as periodic displacement of atoms with an additional periodicity, different from the three unit-cell lattice constants. Any periodic perturbation can be represented by a series of Fourier terms and this is specifically what is used to represent the displacements we are referring to.

Let us reinterpret a structure in superspace with the simplest possible displacement or *modulation* function, i.e., a sinusoidal displacement as represented in Figure 52a. The description of the structure in superspace can be thus analysed in terms of two-dimensional sections just like architect's plans of a complex building are analysed in terms of 2-d sections. Practically, a limited amount of sections is sufficient to fully characterize the structure. From Figure 52b we can see that the real crystal structure is not analysed in terms of the natural

1226 variable  $x_4$  but rather by the variable t which is related to  $x_4$  by the relation  $t = x_4$ -q·r. For the specific case of natrite, it turns out that only four reciprocal basis vectors are necessary to 1227 fully characterize the diffraction pattern with integer coefficients. In general, this is not 1228 always the case and examples of structures with up to six reciprocal basis vectors have been 1229 found. This is for example the case for icosahedral quasicrystals. The number of reciprocal 1230 basis vectors necessary to fully characterize the structure is called the rank. Therefore, if the 1231 rank is equal to the dimension of the periodic object, the structure is *periodic*. Otherwise, if 1232 the rank is larger than the dimension, the structure is *aperiodic*. 1233

As in periodic structures, the resolution of aperiodic crystal structures consists of 1234 determining the electron density (if X-ray are used) from the structure factors by Fourier 1235 transform. For a structure with rank 4, described in (3+1)D superspace, the structure factor 1236  $F(\mathbf{H})$  is given by the relation: 1237

1238

$$F(\mathbf{H}) = \sum_{j} f_{j}(\mathbf{H}) \exp(2\pi i \mathbf{H} \cdot \mathbf{r}_{j}) \\ \times \int_{0}^{1} dt \ p_{j}(t) \exp\{2\pi i (\mathbf{H} \cdot \mathbf{u}_{j}(t) + h_{4}t)\}$$
(5)

1239 On the first line we recognise the classical part of the structure factor with the atomic scattering factors  $f_i$  whereas the second line is dedicated to the modulated part of the structure 1240 which is characterize by the functions  $\mathbf{u}_i(t)$ , for each atom in the unit cell. As mentioned 1241 before, the variable t is more convenient for the analysis of the geometrical characteristics 1242 between atoms and is favoured instead of  $x_4$ . The probability factor  $p_i(t)$  allows to characterise 1243 structures with substitution modulations or defects. 1244

More complex modulation functions  $\mathbf{u}_i(t)$  can obviously be obtained by adding a series 1245 of harmonic terms to optimize the best fitting function. Other possibilities however have been 1246 proposed like crenel or step-like, sawtooth and zigzag functions (Petříček et al. 2014). An 1247 important ingredient for the description of crystal structures concern the space group 1248 symmetry used to characterize periodic structures. For aperiodic structures, however a 1249 generalization of the symmetry concept has been introduced in order to fully describe them, 1250 the so-called superspace groups. This is not our intention to deal here with the theoretical 1251 basis of superspace symmetry. Bibliographic references may be found in Janssen et al. (2008) 1252 and van Smaalen et al. (2013). 1253

One may wonder what kind of structure solutions methods can be applied to solve 1254 aperiodic structures. Fortunately, some efficient and recently developed algorithms have been 1255 designed (see for instance Oszlányi and Sütő 2004; Palatinus and Chapuis, 2007) to solve any 1256 type of structures in any dimension perhaps with some caveat on macromolecular structures. 1257 1258 These methods are based on *dual space phase retrieval algorithms*. They are iterative methods which attempt to estimate the phases of the structure factors (reciprocal space) by 1259 forcing them to satisfy the conditions that the atomic density of the structure (direct space) 1260 cannot be negative. The program package JANA2006 (Petříček et al. 2014) is a very efficient 1261 tool to solve and refine both periodic and aperiodic structures in any dimension. 1262

Finally, we can conclude this paragraph by giving some specific characteristics about 1263 possible aperiodic structures. In our introduction, we have enumerated the three main families 1264 of aperiodic structures which have been identified, namely the incommensurately modulated 1265 structures, the composites and the quasicrystals. According to Yamamoto (1996), the best way 1266 to distinguish the categories is to look at their diffraction patterns which are schematically 1267 represented in Figure 53. In modulated structures, we can always distinguish a series of main 1268 reflections along the external space dimension Re and in addition a series of satellites with 1269 1270 embedding along the internal space dimension R<sub>i</sub>. In composites, we can always distinguish two or more series of main reflections and in addition satellites may also occur. In 1271

1272 quasicrystals however, the distinction between main and satellite reflections can no longer be 1273 made and the important reflections have no periodicities. Quasicrystals can always be clearly 1274 distinguished whereas we can find limiting cases where the distinction between modulated 1275 and composite crystal is not clear cut.

1276 In the next paragraphs, we shall present a few characteristic aperiodic mineral structures 1277 and illustrate their specific properties.

1278

# 1279 **6.3 Natrite**, Na<sub>2</sub>CO<sub>3</sub>

As mentioned earlier, natrite was at the origin of a new revolution of the concept of 1280 crystals. The first hints aroused when de Wolff and his group (Brouns et al. 1964) realised that 1281 they could not fully index its powder diffraction pattern. The solution of the problem was 1282 found a decade later when van Aalst et al. (1976) proposed for the first time the embedding of 1283 the diffraction pattern in higher dimensional space. In addition, they introduced the concept of 1284 high-dimensional symmetry of modulated structures and proposed a structural model of 1285 Na<sub>2</sub>CO<sub>3</sub> in the harmonic approximation. Shortly following this paper, the concept of 1286 1287 superspace symmetry was introduced by de Wolff et al. (1981).

We have to mention at this point that many publications prior to de Wolff's work were published pointing to the existence of modulated structures in various systems. Unfortunately, these studies proposed *ad hoc* structural solutions but failed to develop a valid concept to generalize the symmetry properties which is a prerequisite for any structural studies. The work initiated by the Dutch groups was the trigger which started the rapid development of the new structural paradigm.

Coming back to the structure of natrite, we should mention here that most of the structural studies performed have been done on synthetic samples (Dušek et al., 2003; Arakcheeva and Chapuis 2005). A study by Arakcheeva et al. (2010) comparing natural natrites and synthetic Na<sub>2</sub>CO<sub>3</sub> shows very similar structures with some minor discrepancies in the phase transition temperatures which can easily be explained by various impurities always present in natural samples.

Na<sub>2</sub>CO<sub>3</sub> exhibits numerous phases depending on the temperatures (Dušek et al. 2003;
Arakcheeva and Chapuis 2005) which are schematically indicated below.

1302

α	754K	$\beta$	605K	$\gamma'$	530K	$\gamma$	170K	δ
hexagonal		monoclinic		monoclinic		monoclinic		monoclinic
				incom.		incom.		lockin

1303 1304

1305 The structure of  $\gamma$ -Na<sub>2</sub>CO<sub>3</sub> is best described in terms of graphite-like layers formed by 1306 Na<sup>3+</sup> and CO<sub>3</sub><sup>2-</sup> ions as illustrated in Figure 54. Na1 and Na2 are located between the layers. 1307 Both are coordinated by 6 oxygens forming octahedra. For Na3 however, the octahedra are 1308 strongly distorted. The Na1,2–O distances vary between 2.3 and 2.4Å whereas for Na3–O the 1309 distances vary between 2.5 and 2.9 Å. In all the phases, the distinction between the two Na1,2 1310 and Na3 can always be observed and although they are the same atomic species they behave 1311 like two stereo-chemically distinct groups of atoms.

1312 In order to understand the nature of the incommensurate character of  $\gamma$ -Na<sub>2</sub>CO<sub>3</sub>, let us 1313 analyse this structure in terms of Na and C containing planes illustrated in Figure 55 and 1314 neglect the oxygen atoms. In the inset, we can distinguish two types of planes, namely m<sub>M</sub> and 1315 m<sub>v</sub>. The m<sub>M</sub> plane is the monoclinic (*a*, *c*) plane which can be also seen in Figure 54. The 1316 other m<sub>v</sub> planes are rotated by  $\pm 60^{\circ}$  along the direction of the hexagonal channels.

1317The atomic arrangement of both  $m_M$  and  $m_V$  planes are identical in the high-temperature1318hexagonal phase  $\alpha$ . At T  $\leq$  754 K, the  $m_M$  plane and the corresponding configuration remains1319stable and unchanged in all the lower-temperature phases including the incommensurate ones.

1320 The atomic arrangement observed in the  $m_V$  planes attempts to remain identical to the  $m_M$ 1321 plane but the monoclinic distortion does not allow it. By decreasing temperature from 754 K 1322 down to 605 K, the distortion of the  $m_V$  plane increases in the  $\beta$  phase until it transforms into 1323 the incommensurate  $\gamma$  phase. In the  $\gamma$  phase, the atomic arrangement of the  $m_V$  plane is a 1324 compromise of a sequence of different configurations observed in the  $\beta$  phase at different 1325 temperatures (Fig. 55). This is at the origin of the incommensurability of the  $\gamma$  phase.

1326 It is important to note here the origin of the driving force in the sequence of phases 1327 observed in this compound which is also valid for the incommensurate phase. It is not the 1328 interactions of sodium with its first coordination sphere, i.e., O atoms, but it is the interactions 1329 with sodium with its second coordination sphere consisting of Na and C atoms as shown in 1330 the study by Arakcheeva and Chapuis (2005).

We can follow the evolution of the sequence of phases by focusing on the Na atoms in the vicinity of the C atoms, which gives the following coordination scheme while limiting the C···Na contacts to 3.1Å

1334

Phase	$\alpha$	$\beta$	$\gamma'$	$\gamma$	$\delta$
CN	3	4	5	6 - 7	7

1335 1336

1337 The intra layers contact distances between of C and Na3 atoms remain practically 1338 unchanged over the temperature range. Thus, the increase of coordination number is 1339 essentially due to the Na1,2 channel atoms. None of them participate in the coordination 1340 sphere in phase  $\alpha$  whereas all of them are bonded in the lock-in phase  $\delta$ .

1341 It should be mentioned that a detailed study of structure modulations in natural natrites 1342 from different origins (Arakcheeva et al. 2010) gives valuable information on the history of 1343 the mineral transformation as a function of their occurrences.

#### 1344 1345

### 6.4 Calaverite Au<sub>1-x</sub>Ag<sub>x</sub>Te<sub>2</sub>

Calaverite, a mineral with the composition of Au<sub>1-x</sub>Ag<sub>x</sub>Te<sub>2</sub>, where  $0 \le x \le 0.15$  is an 1346 important gold-bearing ore and another interesting case of a modulated structure which has 1347 first challenged mineralogists and later structural scientists until its secret could be uncovered. 1348 Already in the beginning of the 20<sup>th</sup> century, before the diffraction method was discovered, the 1349 attempts by mineralogists to index the faces of calaverite according to Haüy's law of rational 1350 indices failed. After many attempts to solve this puzzle, an important study was published by 1351 Goldschmidt et al. (1931) presenting an extended analysis of 105 different calaverite samples 1352 originated from all over the world and identified 92 different crystal forms. The conclusion of 1353 their work was that the law of rational indices was not of general validity. They were 1354 obviously right but the tools to solve the problem were not ready yet. 1355

The resolution of the incommensurate structures of calaverite by Schutte and de Boer
(1988) based on the full set of diffracted intensities including satellite reflections was
fundamental to understand the origin of its incommensurability.

The average structure of calaverite solved by neglecting the satellite reflection is 1359 illustrated in Figure 56a. It consists of a series of parallel layers of edge sharing Te octahedra 1360 centred by (Au,Ag) atoms. The geometrical properties of the incommensurate structure can 1361 best be explained in terms of a *t*-plot as introduced in Figure 52. The distance *t*-plot illustrated 1362 in Figure 56b gives all the (Au,Ag)-Te < 3.3 Å distances. Note that *t*-plots conveniently 1363 summarize all the possible configurations which exist in the crystal but do not include 1364 information about orientation and position of the other atoms located in the extended 1365 neighborhood. 1366

1367 The analysis of the *t*-plot indicates that for  $t \approx \frac{1}{4}$  and  $\frac{3}{4}$  (Au,Ag) is surrounded by only 1368 four close Te atoms with (Au,Ag)-Te distances of about 2.7 Å (numbers 1,2,3,4 and 1,2,5,6,

respectively, Fig. 56b). Two other distances of 3.2 Å are too long to take part in the 1369 coordination sphere. Knowing that the corresponding *t*-plot of the angles are close to  $90^{\circ}$ , we 1370 can conclude that somewhere in the crystal space, we shall find square planar (Au,Ag)Te<sub>4</sub> 1371 configurations with the coordination number CN = 4 for (Au,Ag). Other *t*-intervals can be 1372 characterized with CN = 4 + 2. For a deeper analysis of the properties of the structure, we 1373 need to represent a portion of the modulated structure with many basic unit cells. 1374

Figure 57 shows a portion of the  $Au_{0.9}Ag_{0.1}Te_2$  structure with ordered distribution of Ag 1375 (Bindi et al. 2009b). The blue circles indicate sites where Ag replaces some of the Au atoms in 1376 the octahedra with CN = 4+2. The remaining octahedra contain only Au. Schutte and de Boer 1377 (1988) proposed that the origin of the modulation in calaverite was due to the presence of 1378 Au<sup>1+</sup> and Au<sup>3+</sup> with the electronic configuration  $5d^{10}$  respectively  $5d^8$ , since Au<sup>3+</sup> prefers a 1379 square planar coordination with Te. However, X-ray absorption spectroscopy experiments 1380 reported by Ettema et al. (1994) unequivocally shows only Au<sup>1+</sup> in calaverites. This 1381 conclusion is confirmed by a comprehensive structural study by Bindi et al. (2009b) with 1382 examples from a series of calaverites with different Ag compositions  $0 \le x \le 0.33$ . The 1383 modulation of the oxidation state of Au has also been estimated between 0.9 and 1. This study 1384 has demonstrated that the Ag distribution on the Au position plays a key role in the structure 1385 formation. The ordered distribution of silver reinforces the valence fluctuation of Au and the 1386 structure modulation. A random distribution of Ag suppresses the valence fluctuation of Au 1387 and, therefore, their structural modulations. Apparently, natural samples can be found with the 1388 1389 same composition but with both types of Ag ordering, which is not surprising considering the 1390 various growth conditions of the minerals.

Calaverite is a member of a more general family of pseudo-binary system Au<sub>1-x</sub>Ag<sub>x</sub>Te<sub>2</sub> 1391 with a silver content up to x=0.5. In the mineral krennerite, the silver content varies between 1392  $0.2 \le x \le 0.28$ . The mineral sylvanite exists in two forms: one with x = 0.5 and the second 1393 with x slightly smaller than 0.5. It is interesting to note that the superspace model applied to 1394 calaverite is able to reproduce the complete set of structures of the pseudo-binary system by 1395 adapting the modulation vector  $\mathbf{q}$  with commensurate or incommensurate components and 1396 adjusting the *t*-plot of the variable *x*. 1397

Finally, we would like to conclude this paragraph by returning back to the famous 1398 conclusion of Goldschmidt et al. (1931) about the impossibility of indexing the faces and the 1399 1400 rejection of the law of rational indices. Shortly after the resolution of the incommensurate structure of calaverite, Janner and Dam (1989) managed to unambiguously index all the 1401 possible faces identified in the 1931 paper. The solution was to use four indices for each face, 1402 1403 i.e, a number equal to the rank of the structure as previously defined. Figure 58 illustrates the indexation of the faces. Janner and Dam (1989) could identify two twin samples and 1404 moreover, from the measurements of Goldschmidt et al. (1931), they could deduce the exact 1405 1406 components of the modulation vector  $\mathbf{q}$  up to a precision comparable to that obtained by the X-ray diffraction measurements! 1407

The example of calaverite is by no means an exception and other examples have been 1408 found in metal-organic materials where the temperature dependence of the modulation vectors 1409 could be deduced from the observations of the crystal forms (Dam and Janner 1986). 1410

Haüy's law is thus still valid provided that we extend the number of indices to the rank 1411 1412 of the structure.

1413

#### 6.5 Melilite (Ca,Na)<sub>2</sub>(Mg,Fe<sup>2+</sup>,Al)[(Al,Si)SiO<sub>7</sub>] 1414

The group of melilite minerals include generally solid solution of åkermanite and 1415 gehlenite with chemical composition Ca2MgSi2O7 and Ca2Al(AlSiO7), respectively. The 1416 overall formula can be expressed as X2T1T22O7 with T1 and T2 atom species tetrahedrally 1417 coordinated by oxygens. The basic structural features of the mineral family have been known 1418

since the 1930s but the incommensurability was discovered much later by Hemingway et al. 1419 (1986). 1420

The structure of melilite consists essentially of corner sharing tetrahedra layers 1421 alternating with X containing layers as represented in Figure 59. The T2 tetrahedra always 1422 appear in pairs forming bow-tie whereas the T1 tetrahedra are linked to four T2 tetrahedra. 1423 Each layer consists of irregular pentagonal rings surrounded by two T1 and three T2 1424 1425 tetrahedra. The X atoms are located between the tetrahedra layers and are linked to the oxygens of the nearest layers. 1426

It is clear that this structure allows a large degree of freedom to accommodate many 1427 different chemical substitutions for the T1, T2 and X cations. The tetrahedral layers can easily 1428 accommodate different T cations with variable size by permitting rotational and translational 1429 displacements. 1430

Since the discovery of the incommensurate nature of some melilite structures, many 1431 structural studies appeared with various compositions and temperatures. A selection of 1432 references can be found in Bindi et al. (2001). The incommensurate structures have been 1433 solved in (3+2)D superspace group with tetragonal symmetry. The origin of the 1434 incommensurability is essentially due to positional rather than substitutional changes. The 1435 coordination of the X cations by O atoms within a single incommensurate structure may vary 1436 between 6 and 8 and a flattening of the T1 tetrahedra may also occur. Occupational 1437 modulation wave has also been observed in some cases pointing to ordered distribution of 1438 1439 some cations. Superstructures which can also be interpreted as *commensurately* modulated 1440 structures have also been observed.

The resolution of a natural incommensurately modulated melilite sample from Umbria 1441 (Italy) presented here was published by Bindi et al. (2001). Only first order satellites were 1442 observed. A portion of the incommensurate layer structure is presented in Figure 60a. A close 1443 analysis of the pentagonal rings mentioned above shows a large variation of deformation 1444 extending in the layer plane. The most important feature of the deformation can best be 1445 understood in terms of the T1-X coordination sphere as represented in the *t*-plot of Figure 1446 60b. Here we concentrate on the X neighbourhood of T1. We can essentially distinguish two 1447 zones, one in the vicinity of  $t = \frac{1}{2}$  and one in the vicinity of t = 0 or 1. Close to  $t = \frac{1}{2}$  T1 has 8 1448 X neighbours with distances up to 4 Å located approximately on the vertices of a cube (see 1449 1450 inset). Close to t = 0 or 1, T1 has only four X neighbours forming a tetrahedron. Figure 60a illustrates another feature of the structure based on the X-O coordination polyhedra. In the 1451 average structure of melilite they are slightly distorted trigonal prism with 6 oxygens. In the 1452 incommensurate structure, we observe that the 6-coordinated X atoms form clusters with four 1453 long T1-X distances surrounding the T1 tetrahedra indicated on Figure 60a by black 1454 tetrahedra. The clusters are regularly located on various circles with 8 members which recalls 1455 to some extent similar distributions in quasicrystals! The small 8-membered ring has also 1456 been observed in a synthetic Ca<sub>2</sub>CoSi<sub>2</sub>O<sub>7</sub> (Riester et al. 2000) by X-ray diffraction and in 1457 Ca<sub>2</sub>ZnGe<sub>2</sub>O<sub>7</sub> (van Heurck et al. 1992) by electron microscopy. 1458

The X-O polyhedra deformation is certainly not the only distortion observed in melilite. 1459 The T1-O distances and O-T1-O angles are also affected according to various t-plot 1460 calculations. The departure from the ideal angle of 109° may vary between 103 and 123°. 1461

1462 Here again as in the other mineral structures presented above, we can find a common justification for the origin of the incommensurability. In melilite, the presence of impurities 1463 and the relative size of the X and T cations create disparities in the coordination polyhedra. 1464 The ideal 6 coordinated X-O polyhedra can only be accommodated locally, however not 1465 stochastically but in a very ordered way in the form of various circular distributions as 1466 indicated on Figure 60a. 1467

1468

#### 1469 **6.6 Natural Quasicrystals**

The discovery of synthetic quasicrystals by Shechtman et al. (1984) extended further the 1470 concept of aperiodicity in crystals beyond incommensurately modulated and composites 1471 structures. Following this discovery, a large number of Al ternary alloys with quasicrystalline 1472 structures could be produced and analyzed by diffraction methods. Two families of 1473 1474 quasicrystals essentially emerged in these studies, namely icosahedral and decagonal quasicrystals. During that period, it appeared however that the world of mineralogy would 1475 remain exempt of *natural* quasicrystalline materials. The situation changed a quarter of a 1476 century later when Bindi et al. (2009c) discovered the first naturally occurring sample of a 1477 quasicrystal. The discovery did not occur by serendipity but following not only a systematic 1478 analysis of all metallic alloys which could be found in structural databases but also by 1479 analyzing various notable mineral collections (Bindi 2020). Finally, the search focused around 1480 the mineral kathyrkite (Cu,Zn)Al<sub>2</sub> originating from the Koryak Mountains in the northeast of 1481 the Kamchatka Peninsula in Russia. From a sample size of sub-um, the authors could locate 1482 an area which did produce the characteristic diffraction pattern with ten-fold symmetry 1483 1484 illustrated in Figure 61a obtained by HRTEM. The chemical analysis of the sample yielded the composition Al<sub>63</sub>Cu<sub>24</sub>Fe<sub>13</sub>, which is very close to the already known synthetic face-1485 centered icosahedral phase (FCI). In addition to the ten-fold symmetry pattern, the authors 1486 1487 could also locate the six- and two-fold patterns at angles corresponding to the FCI pattern. Another convincing argument of the icosahedral symmetry of the sample is given in Figure 1488 61b. The plot lists the intensity weighted  $|\Delta|$  where  $\Delta$  is the absolute deviation of each 1489 1490 scattering vector **H** from the nearest matching FCI peak versus the intensity-weighted average of H. The center grey zone corresponds to a large number of classical structures extracted 1491 from the ICDD database whereas the symbols ③ and  $\circ$  represent well identified QC 1492 structures. The vertical and horizontal dotted lines represent  $1\sigma$  confidence intervals. It is thus 1493 1494 clear that the mineral ( $\blacktriangle$ ) confirms the nature of its QC structure.

1495 The natural QC mineral was subsequently given the official name *icosahedrite* (Bindi et 1496 al. 2011) and a further analysis (Bindi et al. 2012b) gave evidence of the extraterrestrial origin 1497 of the sample. The formation of the sample was estimated to be approximately 4.5 Gya under 1498 extreme conditions, i.e., shock pressures  $\geq 10$  GPa and temperatures  $\geq 1500$  K. The meteoritic 1499 origin of stable QC forms is thus clearly demonstrated.

1500 The analysis of the famous kathyrkite sample reserved another surprise, namely the 1501 discovery of a decagonal quasicrystalline phase (Bindi et al. 2015) with composition 1502  $Al_{71}Ni_{24}Fe_5$ . This chemical composition has also been observed in synthetic samples. 1503 Decagonal quasicrystals with rank = 5 can be described by a periodic stacking of 1504 quasicrystalline layers. Thus, contrary to the icosahedral QC, only ten-and two-fold symmetry 1505 diffraction pattern can be observed but no six-fold symmetry.

1506 Yet, the kathyrkite sample delivered a third quasicrystalline phase with the chemical 1507 composition  $Al_{62}Cu_{21}Fe_7$  (Bindi et al. 2016b). Contrary to the previously discovered natural 1508 QC, this new icosahedral phase did not have any synthetic equivalent and its composition 1509 seemed to be outside the previously expected equilibrium stability field under standard 1510 pressure. Noteworthy, the synthetic analogue of natural  $Al_{62}Cu_{21}Fe_7$  was recently obtained by 1511 a collision experiment simulating the impact between asteroids in outer space (Hu et al. 1512 2020).

Synthetic QC often exhibits so-called *phason strains*. Phason strains are elastic modes which diffuse in the structure and often relax. They cause systematic shift of the Bragg reflections and the shifts from the ideal positions are inversely related to the intensity of the peak. They are usually observed on samples subject to rapid quenching during the synthesis. It appears that the two natural QC crystalline samples described here are exempt of phason strains and thus depart significantly from synthetic samples formed under strictly controlled 1519 laboratory conditions (Bindi and Stanley 2020). This feature gives also an important indicator1520 about the long-term stability of natural QC phases.

1521

## 1522 6.7 The puzzle of "labradorite"

1523 The variety of anorthite known as "labradorite" is notable for the iridescent effect 1524 observed on some specimens as illustrated in Figure 62a. It belongs to the family of the 1525 plagioclase feldspars with composition  $Ca_xNa_{1-x}Al_{1+x}Si_{3-x}O_8$  which form solid solution with the 1526 two end members *albite* (NaAlSi<sub>3</sub>O<sub>8</sub>) and *anorthite* (CaAl<sub>2</sub>Si<sub>2</sub>O<sub>8</sub>).

Plagioclase feldspars can be considered as an important diagnostic tool for petrological 1527 studies. The nearly continuous composition variable x is at the origin of structural 1528 complexities which have filled many volumes of studies dedicated to a better understanding 1529 of their structures. The observation of superstructures, diffuse scattering and the presence of 1530 satellite reflections in the diffraction patterns have been the subject of many interesting model 1531 proposals since more than 60-70 years. Korekawa and Jagodzinski (1967) were the first to 1532 report the observation of two types of satellite reflections relating to two scale lengths in the 1533 diffraction patterns of labradorite with an anorthite content of 52%. One series of satellites 1534 (called e-satellites) is associated with a modulation periodicity of 50 Å and the other series (s-1535 satellites) is associated with another type of modulation with a much larger periodicity and 1536 which is related to the iridescent (or schiller) effect (Fig. 62b). The periodicity of the violet 1537 color is approximately 1800±200 Å and 1400±200 Å for the ultraviolet. 1538

A more recent publication by Boysen and Kek (2015) attempts to propose an improved model of labradorite on the basis of X-ray synchrotron radiation data. The tentative schematic model illustrated in Figure 63 gives an interpretation of the origin of the two scale lengths. The large domains D1 and D2 exhibit anorthite content differences of up to 10% and are related to the modulation given by the s-satellites. Within each domain D<sub>i</sub>, we observe another modulation sequence related to the e-satellites. The origin of this modulation is also due to variations of the Na/Ca content but the role of the Si/Al distribution is not clarified.

It is surprising that a complete and satisfactory structure solution has not yet been 1546 proposed despite the numerous studies on the problem published up to these days (Jin and Xu 1547 2017). The difficulty lies in finding a single structural model which is capable of handling 1548 simultaneously both types of modulations with two independent and very different length 1549 1550 scales. This would solve the problem of existing correlations with the different Ca/Na and Si/Al contents in different domains and which are completely neglected if the structure 1551 solution neglects one or the other type of satellite. Another difficulty resides in the accurate 1552 measurements of very narrow and weak satellite reflections even on current synchrotron 1553 facilities. It is thus probable that a definitive solution of the structure of labradorite will 1554 possibly emerge from a new refinement in a (3+2)D structure model, i.e., with rank 5 instead 1555 of rank 4. 1556

1557

#### 1558 **6.8 When "disorder" turns out in aperiodicity**

1559 The analysis of aperiodic crystal structures often reveals very subtle atomic interactions 1560 which are difficult to detect with classical structures. This is not only valid for minerals but 1561 for any aperiodic structure. Another interesting aspect is that a single atomic species may 1562 occur in the same structure with different crystal-chemical environments and different valence 1563 states giving clues on its electronic state. This is the case for instance of Na in natrite and Au 1564 in calaverite.

1565 It turns out that the usefulness of the tools which have been developed for the analysis 1566 and solution of aperiodic structures (Petříček et al. 2014) goes much beyond these goals. They 1567 also have been useful for the prediction and design of new structures. They are also helpful in 1568 discovering new relations between various structures as in the case of scheelite (Arakcheeva and Chapuis 2008). The use of the superspace concept is by far not limited to aperiodic structures but represent a very powerful link between the periodic and aperiodic allowing to extend the notion of structure type.

1572 The discovery of aperiodic structure has had an enormous impact on pushing back the 1573 frontier of so-called disordered structures. Before the concept was well established, many 1574 different structures have been published with some caveats on the existence of additional 1575 (usually weak) peaks which could not be explained. They were mostly attributed to 1576 "impurities" or "disorder". It turns out that these structures were very well ordered but with an 1577 aperiodic character.

1578

# 1579 **7. Conclusion and perspectives**

Researches and studies dealing with the complexity of mineral structures are continually 1580 moving forward. In recent years, the new generation of instruments (with new super-sensible 1581 CCD and imaging plate systems) considerably improved the sensitivity of data collection for 1582 1583 complex mineral structures of very small samples, in particular incommensurately modulated and disordered structures. Several computer programs are nowadays able to deal with these 1584 structures. Beside X-ray diffraction, precession electron diffraction methods are increasing 1585 1586 their power allowing the determination of structures from very small particles, down to a few nanometers (e.g., Mugnaioli and Gemmi 2018). Given this extraordinary range of techniques 1587 and instrumentations, we think that, beside the ongoing work to determine still-unknown 1588 1589 mineral structures, a broader vision is called for in considering the future of mineralogical crystallography. Mineralogy can indeed continue to surprise us and have a strong impact on 1590 other disciplines, including chemistry, condensed matter physics, materials science and 1591 engineering. 1592

1593 1594

## Acknowledgements

The first author would like to express his gratitude to Paul Chaikin, who raised the idea 1595 of a review paper on the complexity of mineral structures for the Physics community. He fully 1596 understood the prominent role of mineralogical crystallography in the advancements of 1597 structural science. The manuscript took advantage from the review of two anonymous 1598 reviewers. The research was funded by MIUR-PRIN2017, project "TEOREM deciphering 1599 geological processes using Terrestrial and Extraterrestrial ORE Minerals", prot. 2017AK8C32 1600 (P.I. Luca Bindi). SVK was supported in this work by the Russian Science Foundation (grant 1601 19-17-00038). GC thanks Alla Arakcheeva for the critical reading of some portion of the text 1602 and for her help in the preparation of some drawings. 1603

#### 1987 Figure captions

**Figure 1**. Hexagonal compact layer of equally sized spheres, with the two differently oriented triangular cavities indicated as B and C. The centres of the spheres are indicated as A.

Figure 2. The octahedral (O) and the two tetrahedral (T) cavities in the region between
two compact layers of equally sized spheres in which the spheres in upper layer are positioned
on one of the triangular cavities of the lower layer.

**Figure 3**. The two trigonal prismatic ( $P_1$  and  $P_2$ ) cavities in the region between two compact layers of equally sized spheres in which the spheres in upper layer are positioned above the spheres of the lower layer. This and the following figures, up to Fig. 23, drawn with VESTA (Momma and Izumi 2011).

**Figure 4**. The tetrahedral (T) and octahedral (O) sheets building the layer phyllosilicates (a) Perspective view of the T sheet. (b). The dioctahedral sheet seen along [001]\*. Red spheres are oxygen atoms, smaller white spheres are hydrogen atoms. Dashed segments represent hydrogen bonds. (c). The trioctahedral sheet seen along [001]\*. Same colour scheme as in (b).

2003 Figure 5. The TOT layer seen (a) along [010] and (b) along [001]\*. In (a), the two T sheets are staggered one with respect to the other by about -a/3. In (b), the ideal configuration 2004 2005 of the T sheet (hexagonal) symmetry is shown, which is however seldom realized in phyllosilicates, a ditrigonal rotation of the tetrahedra being very common. Red and blue 2006 spheres are oxygen atoms and hydroxyl groups, respectively. The conventional (rectangular in 2007 projection) and primitive (rhomb-shaped in projection) unit cells are shown. The symmetry 2008 elements of the point group are also shown: a two-fold axis parallel to b (thin line ending with 2009 2010 the oval symbol of a twofold rotation axis), a mirror plane normal to it (thick line) and an inversion centre (small white circle at the intersection of the rotation axis and the mirror 2011 2012 plane).

Figure 6. The real configuration of the T sheet in a trioctahedral (a) and dioctahedral (b) TOT layer. The ditrigonal rotation, which depends on the actual chemistry of the mineral, is in general more important for the dioctahedral layer because of the size difference between the empty and the occupied octahedral sites.

Figure 7. The real structure of the T sheet in talc and pyrophyllite. Two adjacent T sheets belonging to two successive TOT layers, from which the O sheets have been removed. The ditrigonal cavities (ideally hexagonal) have parallel orientation but are shifted by about (a) a/3 for talc (0.2968a) and (b) about 1/10 along the [120] direction for pyrophyllite.

Figure 8. The real structure of the T sheet in micas. Two successive TOT layers from which the O sheets have been removed. Between the two T sheets, the interlayer cation (purple) is shown. Even  $(2n \times 60^\circ)$  orientations result in a staggered configuration of the basal oxygen atoms (Fig. 8a, phlogopite-1*M*), whereas odd  $[(2n+1)\times60^\circ]$  orientation in an eclipsed orientation (Fig. 8b, phlogopite-2*O*, and Fig. 8c, lepidolite-2*M*<sub>2</sub>).

Figure 9. In trioctahedral TOT layers the tetrahedra of the same T sheet have parallel or quasi-parallel orientation (a), whereas in dioctahedral TOT layers, because of the size difference between empty and occupied O sites, these tetrahedra are tilted about the basal bridging oxygen atoms. Figure 10. The interlayer region of 1M polytype of chlorite, containing an isolated O sheet, with two T sheets belonging to successive TOT layers. These are equally oriented by shifted by 0.42a.

Figure 11. The O sheet seen along [001]\*. In red, positions of the hydroxyl groups that 2033 are replaced by apical oxygen atoms of the T sheet when forming the TOT layer. In blue, 2034 2035 hydroxyl groups the remain in the TOT sheet (the white small circles are hydrogen atoms). Octahedral sides with OH groups in trans configurations are shown in white, those with OH 2036 groups in cis configuration in yellow. replace two thirds of the hydroxyl groups of the O 2037 sheets. The remaining OH groups allow to differentiate the octahedral sites. The rhombic-2038 2039 shaped primitive unit cell, shown in the figure, contains one trans and two cis octahedral 2040 sites; the origin has been moved onto the *trans* site to enhance readability of the figure.

Figure 12. Selection of  $R_5$  (a) and  $R_8$  (b) rods from the TOT layer. Numbers identify the octahedra spanning the width of the rod.

**Figure 13.** The structure of amphiboles, seen along [001]. This structure can be interpreted as composed by  $R_5$  rods, periodic along the *c* axis of the mineral, displaced one with respect to the other along the *a* axis, according to the OH-O<sub>b</sub> bonding scheme. Depending on cations occupying the O chain and the nature of the X cation amphiboles are classified in a number of different minerals. In some of these, the empty space  $\Box$  is sometimes occupied by a monovalent cation, mainly sodium.

Figure 14. The structure of jimthompsonite, seen along [001]. This structure can be interpreted as composed by  $R_8$  rods, periodic along the *c* axis of the mineral, displaced one with respect to the other along the *a* axis, according to the OH-O<sub>b</sub> bonding scheme.

Figure 15. The structure of chesterite, seen along [001]. This structure can be interpreted as composed by  $R_5$  and  $R_8$  rods alternating, according to the OH-O<sub>b</sub> bonding scheme, i.e. by an alternation of amphibole-like modules and jimthompsonite-like modules.

Figure 16. The structure of palygorskite, seen along [001]. This structure can be interpreted as composed by  $R_5$  rods, periodic along the *c* axis of the mineral, displaced one with respect to the other along the *a* axis, according to the O<sub>b</sub>-O<sub>b</sub> bonding scheme. Water molecules occur in the regions between the rods.

Figure 17. The structure of sepiolite, seen along [001]. This structure can be interpreted as composed by  $R_8$  rods, periodic along the *c* axis of the mineral, displaced one with respect to the other along the *a* axis, according to the O<sub>b</sub>-O<sub>b</sub> bonding scheme. Water molecules occur in the regions between the rods.

Figure 18. The structure of kalifersite, seen perspectively along [001]. This structure can be interpreted as composed by an alternation of  $R_3$  rods and  $R_6$  rods, periodic along the *c* axis of the mineral, displaced one with respect to the other along the *a* axis, according to the O<sub>b</sub>-O<sub>b</sub> bonding scheme.

Figure. 19. The structure of wollastonite,  $CaSiO_3$ . (a) Projection along the *b* axis, showing that the O chain has a width of three octahedra. (b) projection along [101]\*, with the cation sites in a ball-and-stick representation. The period of the tetrahedral chain, between two horizontal black lines, is three tetrahedra.

Figure 20. The structure of pyroxenes,  $MSiO_3$  (M = Ca, Mg for diopside, shown in this figure) seen (a) along [001] and (b) along [101]. The larger site, white polyhedron in (a), usually indicated as M2 in the literature, is assimilated to an octahedron for the sake of

comparison with the other structure, although in pyroxenes it does have a octahedral 2074 geometry. The period of the tetrahedral chain, between two horizontal black lines, is two 2075 tetrahedra. Structural data from Cameron et al. (1973). 2076

Figure 21. The structure of rhodonite,  $(Mn^{2+}, Fe^{2+}, Mg, Ca)SiO_3$  seen along [100]\*. The 2077 period of the tetrahedral chain, between two horizontal black lines, is five tetrahedra. This 2078 2079 structure is composed by a regular alternation of wollastonite-like slabs and pyroxene-like slabs, shown between horizontal red lines. Structural data from Peacor et al. (1978). 2080

Figure 22. The structure of pyroxmangite, MnSiO<sub>3</sub>, seen along [100]\*. The period of 2081 the tetrahedral chain, between two horizontal black lines, is seven tetrahedra. This structure is 2082 2083 composed by a regular alternation of one wollastonite-like slabs and two pyroxene-like slabs, 2084 shown between horizontal red lines. Structural data from Pinckney and Burnham (1988).

Figure 23. The structure of ferrosilite-III, FeSiO<sub>3</sub>, seen along [110]\*. The period of the 2085 tetrahedral chain, between two horizontal black lines, is nine tetrahedra. This structure is 2086 composed by a regular alternation of one wollastonite-like slabs and three pyroxene-like 2087 2088 slabs, shown between horizontal red lines. Structural data from Weber (1983).

Figure 24. The  $[(UO_2)_{24}(CO_3)_{30}O_4(OH)_{12}(H_2O)_8]$  cluster in ewingite (a), its skeletal 2089 representation (b), the U core (c; the U–U contacts shorter than 4 Å are shown as thick black 2090 lines; those between 4 and 6.2 Å as thin black lines; red and blue points indicate centres of the 2091 U<sub>3</sub> trimers and midpoints of the shared U–U edges of the U<sub>4</sub> dihedra, respectively), and the 2092 arrangements of the red and blue circles that correspond to the intersection of tetrahedron and 2093 octahedron, respectively (d). 2094

Figure 25. The  $[As^{3+}V^{4+}_{2}V^{5+}_{10}As^{5+}_{6}O_{51}]$  cluster in morrisonite in polyhedral (a) and 2095 2096 skeletal (b) representations.

Figure 26. The projection of the crystal structure of ilmajokite alog the c axis. Legend: 2097 Si tetrahedra = yellow, Ti octahedra = blue;  $H_2O$  molecules, Na, K, Ba, and Ce atoms are 2098 2099 shown as red, light-blue, green, brown, and orange spheres, respectively (after Zolotarev et al. 2020). 2100

Figure 27. Trigonal-prismatic titanosilicate (TPTS) clusters in the crystal structure of 2101 ilmajokite shown in polyhedral (a, c) and nodal (b, d) representations. The numbering scheme 2102 corresponds to the numbering of Si and Ti atoms from the experiment. The Ce-centered Ti<sub>6</sub> 2103 trigonal prism is highlighted in yellow. Legend as in Figure 26 (after Zolotarev et al. 2020). 2104

Figure 28. The hierarchial organization of the crystal structure of ilmajokite separated 2105 2106 into eight hierarchy levels (highlighted in grey).

Figure 29. The crystal structure of langbeinite, K<sub>2</sub>Mg<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> (Mereiter 1979), projected 2107 down [001]. (SO<sub>4</sub>)-tetrahedra are given in yellow and (MgO<sub>6</sub>)-octahedra in green. Purple and 2108 2109 red circles indicate K and O atoms, respectively. The unit cell and the orientation of the 2110 structure are outlined.

Figure 30. The crystal structure of brizziite, NaSbO<sub>3</sub> (Olmi and Sabelli 1994). (SbO<sub>6</sub>)-2111 octahedra are given in green. Yellow and red circles indicate Na and O atoms, respectively. 2112 The unit cell and the orientation of the structure are outlined. 2113

Figure 31. Structure of  $(Ag,Cu)_{16}(As,Sb)_2S_{11}$ , showing the stacking of the 2114 [(Ag,Cu)<sub>6</sub>(As,Sb)<sub>2</sub>S<sub>7</sub>] and [Ag<sub>9</sub>CuS<sub>4</sub>] layers (see text). The former layer is shown as ball-and-2115 stick, with grey, violet, and yellow circles representing (Ag,Cu)1, (As,Sb), and S sites, 2116 respectively. In the latter layer, the positions of Ag atoms (grey circles), are those obtained at 2117 2118 RT; Cu is shown as blue circles.

Figure 32. Non-harmonic joint probability density iso-surface for Ag at RT in the 2119 [Ag<sub>9</sub>CuS<sub>4</sub>] layer extended with S2 atoms, exhibiting the Ag diffusion in the *ab* plane. Level of 2120 the map: 0.05 Å<sup>-3</sup>. Sulfur and Cu atoms are shown at arbitrary sizes. 2121

Figure 33. Projection of the crystal structure of polybasite-221 along the hexagonal *a* axis. Silver, Cu, Sb, and S atoms are shown as grey, blue, brownish, and yellow circles.

Figure 34. Projection of the crystal structure of polybasite-222 structure along the monoclinic *b* axis, emphasizing the succession of the  $[(Ag,Cu)_6Sb_2S_7]^2$  A (A<sub>0</sub>) and [Ag<sub>9</sub>CuS<sub>4</sub>]<sup>2+</sup> B (B<sub>0</sub>) module layers. Same symbols as in Figure 5.

Figure 35. Different unit-cell type in the pearceite-polybasite group of minerals.

Figure 36. Projection of the crystal structure of fettelite along the monoclinic *b* axis, emphasizing the succession of the  $[Ag_6As_2S_7]^{2-}A$  and  $[Ag_{10}HgAs_2S_8]^{2+}B$  module layers. Grey, dark violet, red and yellow circles indicate Ag, As, Hg and S atoms, respectively. The unit cell is outlined.

Figure 37. Non-harmonic joint probability density iso-surface for Ag/Hg in the HTstructure of fettelite exhibiting the Ag diffusion in the *ab* plane. Part of the *B* layer extended with S atoms. Level of the map:  $0.05 \text{ Å}^{-3}$ . Sulfur atoms in arbitrary size.

Figure 38. (a) Three-dimensional representation of a joint probability density isosurface (at the 90 Å<sup>-3</sup> level) for the gamma form of  $Ag_7PSe_6$  at 473 K, showing Ag diffusion paths within a cluster centered on Se3. Se atoms are represented as spheres of arbitrary size (Evain et al. 1998). (b) Three-dimensional representation of a joint probability density isosurface (at the 20 Å<sup>-3</sup> level) showing the cluster connection around the Se2 atom. Se atoms are represented as spheres of arbitrary size and the Se2 splitting is not taken into account for the sake of clarity (Evain et al. 1998).

**Figure 39.** Spryite,  $Ag_8(As^{3+}_{0.5}As^{5+}_{0.5})S_6$ , equant crystals surrounding proustite (Ag<sub>3</sub>AsS<sub>3</sub>) crystals on Mn-bearing calcite. Field of view 1.6 cm.

Figure 40. Crystal structure of spryite as seen down [010] (a). White, light blue, red, and yellow circles correspond to Ag, (Ge,  $As^{5+}$ ),  $As^{3+}$  and S, respectively. (b) Portion of the crystal structure of spryite highlighting the split *M*1-*M*2 positions (see text for explanation). In light blue the *M*1 tetrahedron and with a red circle the *M*2 atom.

Figure 41. Unusual cylindrical aggregates of thin robinsonite fibers from the Monte Arsiccio mine, Apuan Alps, Tuscany, Italy. The aspect ratio of these aggregates, where fibers can show thickness down to less than 500 nm, are larger than 100,000.

**Figure 42.** Sulfosalt structures showing the three main categories of rod-based structures, i.e., rod layers (boulangerite,  $Pb_5Sb_4S_{11}$  – a), chess-board (izoklakeite, (Cu,Fe,Ag)<sub>2</sub>Pb<sub>27</sub>(Sb,Bi)<sub>19</sub>S<sub>57</sub> – b), and cyclic (zinkenite,  $Pb_9Sb_{22}S_{42}$  – c).

Figure 43. The crystal structure of chovanite, seen down *b*, shown as an example of boxwork structure. Different colors indicate walls (yellow), partitions (light blue), and fill elements (pink). Light blue ellipses indicate the lone-electron-pair micelles, whereas red triangles show the pseudotrigonal axes. Dotted lines indicate the surfaces of weakest bonding.

Figure 44. Two different kermesite-like configurations observed in scainiite. In (a), a Sb<sub>2</sub>O<sub>2</sub> ladder can be recognized, whereas (b) shows Sb–O chains (i.e., half of the ladder). The configuration shown in (b) has been reported in several other lead-antimony oxy-sulfosalts. Oxygen, S, Sb, and Pb atoms are shown as red, yellow, brownish, and grey circles, respectively.

Figure 45. The crystal structure of vurroite, as seen down *a*. Circles represent Pb (grey),
Bi (violet), As (dark violet), S (yellow), and Cl (green) sites. Sn sites are shown as brown
polyhedra.

Figure 46. Structural details of the sterryite – parasterryite pair. (a) Crystal structure of sterryite as seen down *a*; (b) complex column of sterryite. The red ellipse indicates the short arm, whose arrangement is shown in (c). Parasterryite has a similar complex column (d), differing mainly for the short arm (red ellipse), shown in (e). Ag, Cu, Pb, Sb, As, and S atoms are shown as grey, blue, dark grey, brownish, dark violet, and yellow circles, respectively.

Figure 47. The two complex columns characterizing the crystal structure of 2171 meerschautite (a, c) and details of their short arms (b, d). 2172

Figure 48. Meneghinite, as lead grey striated prismatic crystals, up to 1 cm long, 2173 associated with siderite and quartz, from the Bottino mine (Tuscany, Italy) (a) and its crystal 2174 structure as seen down the 4 Å axis. Copper, Pb, Sb, and S atoms are shown as blue, dark 2175 grey, brownish, and yellow circles, respectively. 2176

Figure 49. Merelaniite, black whiskers up to  $\sim 3 \text{ mm}$  in length associated with tabular 2177 colorless crystals of "stilbite", showing inclusions of black flattened crystals of graphite. The 2178 specimen is from Merelani, Lelatema Mountains, Tanzania. 2179

Figure 50. Reconstructed reciprocal space layer of natrite with indices of diffraction 2180 reflections h2l. In addition to the main reflections at the lattice nodes h2l defined by the two 2181 vectors  $\mathbf{a}_1$  and  $\mathbf{a}_3$ , we observe a series of equidistant reflections aligned along the vector  $\mathbf{q}$ 2182 called satellite reflections. 2183

Figure 51. Embedding of the three-dimensional reciprocal space into a higher 2184 dimensional space called superspace. The additional reciprocal space vector  $\mathbf{a}_{s4}^*$  consists of 2185 2186 two components, the *external* component **q** and the *internal* component  $\mathbf{e}_4^*$ .

Figure 52. (a) A sinusoidal displacement modulation along  $a_2$ . The period of the 2187 modulation  $\lambda$  is the inverse of  $\|\mathbf{q}\|$ . Corresponding 2-dimensional section in the  $\mathbf{a}_{s2}$ ,  $\mathbf{a}_{s4}$  plane. 2188 The displacements from the average positions along  $\mathbf{a}_2$  is given by the intersections of the 2189 sinusoidal curve along the "real crystal" line. 2190

Figure 53. Distinction between the three families of aperiodic structures based on their 2191 2192 reciprocal space embeddings.

Figure 54. Portion of  $\gamma$ -Na<sub>2</sub>CO<sub>3</sub>, the room temperature phase of natrite. Oxygen forming 2193 triangular coordination around the C atoms (black) are omitted. The links between atoms are 2194 contact distances between Na and C atoms shorter than 3.4 Å. The structure can be interpreted 2195 as a series of parallel graphite-like C-Na3 layers stacked along the c axis. Na1 and Na2 are 2196 located between the layers. 2197

Figure 55. Analysis of the incommensurate structure of  $\gamma$ -Na<sub>2</sub>CO<sub>3</sub> in terms of the m<sub>M</sub> 2198 and m<sub>v</sub> planes containing the Na and C atoms. Links are only indicated for Na, C contact 2199 distances smaller than 3.1 Å. 2200

Figure 56. (a) Average structure of calaverite consisting of parallel edge-sharing layers 2201 2202 of Te octahedra with (Au,Ag) atoms at their centre. (b) t-plot representation of the (Au,Ag)-Te distances from the refinement in superspace in the incommensurate structure of  $Au_{0.9}Ag_{0.1}Te_2$ 2203 with ordered Ag distribution. Numbers refer to the six independent (Au,Ag)-Te distances in 2204 2205 each [(Au,Ag)Te<sub>6</sub>]-octahedron.

Figure 57. Portion of the incommensurate structure of Au<sub>0.9</sub>Ag<sub>0.1</sub>Te<sub>2</sub> with ordered 2206 distribution of Ag on the Au position. The thick grey lines indicate the (Au,Ag)–Te distances 2207 shorter than 3.1 Å. The blue circles represent the (Au,Ag) positions, which incorporate Ag. 2208

Figure 58. Indexation of the calaverite faces by Janner and Dam (1989) with four 2209 indices according to the crystal model of Goldschmidt et al. (1931). The colors indicate the 2210 two twin components. 2211

Figure 59. The average melilite layer structure with general composition  $X_2T1T2_2O_7$ 2212 viewed along the normal to the layers (a) and in the perpendicular direction (b). X atoms are 2213 2214 violet. The blue T2 tetrahedra always form bow tie whereas the yellow T1 tetrahedra are always surrounded by four T2 tetrahedra. 2215

Figure 60. (a) Representation of a layer portion of a natural melilite with an 2216 incommensurately modulated structure and composition (Ca,Na)<sub>2</sub>(Al,Mg,Fe<sup>2+</sup>)[(Al,Si)SiO<sub>7</sub>]. 2217 The black T1 tetrahedra are those surrounded with only six coordinated X-O distances and 2218 four T1-X distances. (b) t-plot of the T1-X (Mg-Ca) distances. Two zones can be 2219 distinguished, one with  $t \cong \frac{1}{2}$  where 8 X atoms (violet) can be found in the vicinity of T1 2220

- 2221 (yellow) with distances shorter than 4.0 Å and  $t \approx 0$  or 1 where 4 X can be found within the 2222 same limit.
- Figure 61. (a) HR TEM diffraction pattern of icosahedral QC  $Al_{63}Cu_{24}Fe_{13}$  with ten-fold symmetry. (b) See text for the explanation of the plot.
- Figure 62. (a) Iridescent "labradorite", a plagioclase feldspar with composition  $Ca_x Na_1$ .
- 2226  ${}_{x}Al_{1+x}Si_{3-x}O_{8}$ . (b) Schematic representation of the main and satellite reflections based on 2227 Boysen and Kek (2015) data.
- Figure 63. Schematic model of the labradorite structure with two different types of domains as proposed by Boysen and Kek (2015). The large domains  $D_i$  are linked to the ssatellites and also to the iridescent property whereas the smaller domains are linked to the esatellites.
