We present an experimental and theoretical study of Pauli paramagnetism and martensite stabilization in a near equiatomic NiTi shape memory alloy. We demonstrate a direct correlation between strain-induced shear of the B19' NiTi lattice and its electronic and thermodynamical features. An increase of the monoclinic angle $\beta$ from 97.4 to 98 degrees induces a 7% decrease of the magnetic susceptibility because of a shift and deepening of a dip in B19' density of state at the Fermi level. It also produces a decrease of the B19' enthalpy, which translates into an increase of the martensite-to-austenite transition temperature by 60 K.

Near equiatomic NiTi alloys carry remarkable properties such as shape memory effect and pseudoelasticity. Both effects are born of first-order reversible phase transformation between low-symmetry monoclinic B19' martensite phase and high-symmetry cubic B2 austenite phase. Tuning the transition temperatures and martensite transformation hysteresis has been a constant objective. It has yet been achieved by adjusting Ni$_{1-x}$Ti$_x$ concentration [1] or by substituting element in ternary NiTiX alloys (with X=Hf, Pd, Cu,...)[2,3]. Geometrical compatibility of B19' and B2 phases [4], change of valence electron number [5] and thermodynamics [1,6] have been investigated to explain the influence of these chemical changes on NiTi-based alloys characteristics. Interestingly, no direct correlation between electronic features, transition temperatures and NiTi lattice distortion for a fixed concentration has yet been demonstrated, whereas the complex microstructure of NiTi under strain has been heavily studied [7-9]. Moreover, magnetism, which is known as a good probe of the electronic properties, has been rarely studied in NiTi alloys [10-13], although its impact on the magnetic resonance imaging of NiTi-based stents and biomedical implants has often been highlighted [14,15].

Here, we perform systematic X-ray diffraction (XRD) and magnetization measurements in order to characterize the influence of the tensile strain on both the martensite-to-austenite transition temperature and magnetic susceptibility of a NiTi sheet. Ab-initio calculations correlate the measured strain-induced shear of the martensite lattice to particular features of the B19' energy and density of states at the Fermi level.

We use NiTi (50.6 at% Ti; 49.4 at% Ni ± 0.5%) free-standing polycrystalline 20µm thick sheets, grown by DC magnetron sputtering as described in details in Ref. [16]. Fig.1 shows the DC Magnetic susceptibility $\chi$ measured by SQUID magnetometer as a function of temperature under a constant magnetic field of 2T. Magnetic field is applied in the plane of the NiTi sheet. Note that $\chi$ does not depend on the measurement direction in the film plane because of the polycrystalline nature of the NiTi sheet. As-grown NiTi sample overcomes a hysteretic transition between a value $\chi_M=23$ mJ.T$^{-2}$.kg$^{-1}$ in the martensite phase and $\chi_A=32.5$ mJ.T$^{-2}$.kg$^{-1}$ in the austenite phase, in agreement with [10]. A magnetic transition temperature of around 360 K (330K) matches the martensite-to-austenite transition in XRD curves, in agreement with [8,17] for similar concentrations. Tensile tests are performed using a Deformation Device System.

Figure 1. Magnetic susceptibility $\chi$ of NiTi versus temperature for as grown sample (black curve), 5% strained sample (red curve), 16.5% strained sample (blue curve).

commercialized by Kammrath & Weiss at 2 μm/s and room temperature, i.e. in the martensite phase. During stretching, elongation of the specimen is measured by a linear displacement gauge while the corresponding force is recorded. 3D strain fields, obtained by the ARAMIS 6M DIC system, confirms the good homogeneity of strain magnitudes over the useful zone of specimens. All details can be found in our previous report [18].

In Fig. 1, red and blue curves show \( \chi \) as a function of temperature during the martensite-to-austenite transformation of the 5% (red) and 16.5% (blue) strained NiTi sample. They are compared to \( \chi(T) \) cycle of the non-deformed NiTi sample (in black). Stretching modifies the magnetic response of NiTi in two ways. First, the martensite-to-austenite transition temperature (so-called Austenite start temperature \( A_s \)) is pushed toward higher temperature when strained, up to 415K in case of 16.5% strain. The positive shift increases linearly with increasing strain (see Fig. 2(b)). This effect, known as stress-induced martensite stabilization and whose origin is still under debate [4-6,19], is one of the two phenomena which we focus on here. In Fig. 1, the second noticeable difference between the as grown and strained samples is the difference between magnetic susceptibility values at 300K in B19' phase (\( \chi_{B19'} \)), whereas austenite susceptibility (\( \chi_A \)) is preserved at high temperature. Fig. 2(a) summarizes all our magnetic susceptibility measurements as a function of strain. \( \chi_M \) is found to decrease monotonically when strain amplitude increases.

In order to access average lattice parameters as a function of temperature and strain, and to later use them in ab-initio calculations, we perform X-ray diffraction measurements (XRD) with a Co Kα source. Heating is accomplished in-situ by means of a DHS 1100 oven at atmospheric pressure (Figure 3(a)). The measured lattice parameters of the unstrained B19' phase at 300K are: \( a = 2.894\,\text{Å}, \quad b = 4.115\,\text{Å}, \quad c = 4.637\,\text{Å} \) and \( \beta = 97.41 \,\text{deg} \), which are close to previous theoretical reports [20,21]. The B2 austenite phase parameter is \( a_A = 3.016 \pm 0.002 \,\text{Å} \). To analyze the strain-induced change of martensite lattice, XRD is
performed for five representative samples with various strain values ranging from 0 to 16% (Figure 3(a)). The monoclinic angle \( \beta \) of the B19' phase increases with tensile strain and tends to saturate at high strain values. The saturation is due to the increasing amount of energy relaxation via plastic deformation (see Fig.3a). The same tendency as of \( \beta \) is observed for both \( a \) and \( c \) parameters while it is inversed for \( b \). In Figure 3 (b), a relative change of \( a, b \) and \( c \) parameters as a function \( \beta \) matches quantitatively well earlier theoretical predictions obtained by ab-initio calculations for relaxed B19’ lattices with fixed \( \beta \) [20,21]. Significant deviation only occurs for the 16% strained sample, most probably due to large level of plastic deformation. Interestingly, the austenite lattice parameter measured by XRD after heating, is found to be insensitive to the level of strain applied to the martensite state, and \( 1.38 \) states.\( \text{atom}^{-1} \) originates from the appearance of a DOS dip at \( E_F \) calculated by Bihlmayer et al. [28]. This discrepancy must allow to tune the density of states at \( E_F \) and finally magnetic susceptibility.

Based on the XRD data, density Functional Theory (DFT) calculations of NiTiB2 are performed with the Vienna Ab-initio Simulation Package (VASP) [22]. The interactions between the valence electrons and the ionic core is described using the projector-augmented wave (PAW) method and the calculations are performed with the generalized gradient approximation (GGA-PBE) [23,24]. Spin polarization is considered. A plane wave basis set for electron wave functions with cutoff energy of 500 eV is used. Integrations in the Brillouin zone are performed using a \( k \)-grid generated according to the Monkhorst-Pack scheme: 33x33x23 for the martensite NiTi. Density of states (DOS) calculations are performed with the tetrahedron method for Brillouin-zone integrations [25]. Atomic positions used for B19’ in all calculations are for Ni: \( x=0.0372 \), \( y=0.1752 \) and for Ti: \( x=0.4176 \), \( y=0.7164 \). B2 and B19’ total DOS as a function of energy are presented in inset in Fig.4(a). Our DFT calculations show no net atomic magnetic moment at rest for both crystal structures. The DOS at the Fermi level \( D(E_F) \) is 0.72 states.\( \text{atom}^{-1} \) eV\(^{-1} \) for the martensite phase and 1.38 states.\( \text{atom}^{-1} \) eV\(^{-1} \) for the austenite phase. It is interesting to note that both values agree well with two previous DFT calculations [26,27] but the martensite one is 25% lower than another value calculated by Bihlmayer et al. [28]. This discrepancy originates from the appearance of a DOS dip at \( E_F \) (Fig. 4(a)) when considering a monoclinic angle around 97.8 deg as in Ref. [26,27] while this dip is much reduced for an angle of 96.8 deg as in Ref. [28]. We calculate that this dip at \( E_F \) originates mostly from Ni and Ti d orbitals, which contribute equally to Pauli paramagnetism. Therefore, tuning of \( \beta \) must allow to tune the density of states at \( E_F \) and finally magnetic susceptibility.

Using our DFT results in equation of Pauli susceptibility in the nearly-free electron model, \( \chi_{\text{Pauli}} = \mu_0^2 D(E_F) \), and subtracting Landau diamagnetic term (1/3 of \( \chi_{\text{Pauli}} \)), we obtain theoretical values: \( \chi_{\text{Pauli}} = 2.9 \) \( \mu_0^2 \text{B} \), \( \chi_{\text{Pauli}} = 5.5 \) \( \mu_0^2 \text{B} \) in martensite phase and \( \chi_{\text{Pauli}} = 5.5 \) \( \mu_0^2 \text{B} \) in austenite phase. Experimental values are 7.6 and 5.8 times larger respectively. Similar discrepancy is reported for many Pauli paramagnetic metals such as Pd (factor of 10) [29] or NiCuZn (factor of 6) [30]. Electronic exchange interaction in nearly-free electron model [29-31] account for such an enhancement of magnetic susceptibility. In NiTi, we find an interaction energy of 1.1 eV in B19’ and 0.55 eV in B2, in line with an earlier analytical prediction by Mitchell et al. [11]. In Fig. 4(a), DOS as a function of energy is
zoomed-in around $E_F$ and plotted for the different B19’ unstrained and strained B19’ lattices found by XRD in Fig. 3. We extended our set of theoretical data with one more point at lower $\beta$ angle ($\beta = 97.3^\circ$) considering the lattice parameters calculated in Ref. [20]. As $\beta$ increases, $D(E_F)$ is found to decrease because DOS dip at $E_F$ shifts toward larger energy, gets deeper and wider. An overall decrease of $D(E_F)$ by 0.04 atom$^{-1}$ eV$^{-1}$ as observed in Fig. 4(a) would translate to a reduction of $\chi_F$ by 1.2 mJ T$^{-2}$ kg$^{-1}$, in good agreement with the experimental data in Fig. 2(a). Therefore, we conclude that NiTi is an exchange-enhanced Pauli paramagnet whose magnetic susceptibility is sensitive to strain because of its dependence to B19’ lattice shear.

The correlation between $\chi_F$ and $\beta$ is revealed when comparing Fig. 2(b) and Fig. 3(a). Between 0 and 10% strain, $\beta$ linearly increases by 0.5 degrees as the shear increases linearly by 40 K. Although here only the shear is affected and no chemical modification are operated, the correlation ratio 80 K/ deg is quite similar to those of NiTi reported in the literature [6,20], as schemed in inset of Fig. 4(b). The correlation ratio 80 K/ deg is quite similar to those obtained when tuning Hf concentration in NiTiHf [2] or when tuning Ni concentration in NiTi [1].

To enlighten the origin of the influence of B19’ shear on $\chi_F$ increase with tensile strain, the difference of energy (enthalpy) between B19’ and B2 state, $E_{B2}$-$E_{B19'}$, calculated for 0K, is plotted in Fig. 4(b) as a function of $\beta$ angle. It rises when $\beta$ is enhanced. In other words, the calculated B2 energy being constant with strain (since the measured lattice parameter by XRD is constant), only B19’ energy is found to decrease by 0.6 meV atom$^{-1}$ when $\beta$ increases by 0.5 degrees. Such decrease of energy for NiTiB19’ state with increasing $\beta$ agrees with the many ab-initio calculations at 0K reported in the literature [6,20]. The link between the variation of enthality at 0 K and the martensite-to-austenite transition temperature above room temperature can be understood by considering the difference of free energy $G_{B2}$-$G_{B19'}$ = ($H_{B2}$-$H_{B19'}$) + $T^\circ$($S_{B2}$-$S_{B19'}$) where G is the free energy, H is the enthality at 0K, $T$ the temperature and S the entropy. Due to the significant difference of phonon-based entropy of B2 and B19’, $S_{B2}$-$S_{B19'}$ almost linearly decreases with increasing temperature and reaches zero for a value just below $\chi_F$ [1,6], as schemed in inset of Fig. 4(b). Therefore, any variation of enthality at 0K leads to a shift of $\chi_F$. We conclude that martensite stabilization can be produced in NiTi, without changing its composition, by engineering strain-induced shear of B19’ lattice.

In summary, we present X-ray diffraction and magnetometry studies of a Ni$_{50}$Ti$_{50}$ alloy free standing film as a function of tensile strain amplitude. We characterize a strain-dependent shear-like trend in B19’ lattice with the monoclinic angle $\beta$ increasing from 97.4 to 98 deg, which we correlate to a reduction of magnetic susceptibility ($\chi_F$) and a raise of martensite-to-austenite transition temperature ($\chi_F$).

Using DFT calculations, we show that dependence in of NiTi exchange-enhanced Pauli paramagnetism originates from the shift and the deepening of a density of state dip at the Fermi level, while strain-induced martensite stabilization is coherent with the lowering of B19’ state enthality with shear.
