26 glacial geomorphology; last deglaciation; Termination 1; continental paleotemperature and precipitation  
27 reconstruction, global and regional climate.

## 28 **Highlights**

- 29 - Cosmic ray exposure ages and paleo-ELAs determined for Bolivian Andes late-glacial moraines
- 30 - New <sup>14</sup>C shoreline ages constrain the depth of paleolake Coipasa (~12.5 cal kyr BP)
- 31 - Temperature and precipitation reconstructed from coupled glacier-lake modeling
- 32 - Lake-induced precipitation recycling effect accounted in reconstruction
- 33 - Precipitation modulated by Northern Hemisphere, temperatures by Antarctic during 19–11 ka BP

## 34 **Abstract**

35           The respective impacts of Northern and Southern Hemispheric climatic changes on the Tropics  
36 during the last deglaciation remain poorly understood. In the High Tropical Andes, the Antarctic Cold  
37 Reversal (ACR, 14.3-12.9 ka BP) is better represented among morainic records than the Younger Dryas  
38 (12.9-11.7 ka BP). However, in the Altiplano basin (Bolivia), two cold periods of the Northern  
39 Hemisphere (Heinrich Stadial 1a, 16.5-14.5 ka BP, and the Younger Dryas) are synchronous with (i)  
40 major advances or standstills of paleoglaciers and (ii) the highstands of giant paleolakes Tauca and  
41 Coipasa.

42           Here, we present new cosmic ray exposure (CRE) ages from glacial landforms of the Bolivian  
43 Andes that formed during the last deglaciation (Termination 1). We reconstruct the equilibrium line  
44 altitudes (ELA) associated with each moraine and use them in an inverse algorithm combining  
45 paleoglaciers and paleolake budgets to derive temperature and precipitation during the last deglaciation.

46           Our temperature reconstruction ( $\Delta T$  relative to present day) yields a consistent regional trend of  
47 progressive warming from  $\Delta T = -5$  to  $-2.5$  °C during 17–14.5 ka BP, followed by a return to colder  
48 conditions around  $-4$ °C during the ACR (14.5-12.9 ka BP). The Coipasa highstand (12.9-11.8 ka BP)  
49 is coeval with another warming trend followed by  $\Delta T$  stabilization at the onset of the Holocene (ca. 10  
50 ka BP), around  $-3$ °C. Our results suggest that, during the last deglaciation (20 – 10 ka BP) atmospheric  
51 temperatures in the Tropical Andes mimicked Antarctic variability, whereas precipitation over the  
52 Altiplano was driven by changes in the Northern Hemisphere.

## 53 **1. Introduction**

54           The last deglaciation was characterized by major reorganizations of the continental and oceanic  
55 climate systems, including modifications of oceanic circulations (McManus et al., 2004), and the  
56 monsoon systems (Cruz et al., 2005), shifts of the wind belts (Denton et al., 2010; Toggweiler, 2009),  
57 and opposing north/south temperature variations (Barker et al., 2009; Broecker, 1998). During this  
58 period, antiphase warming/cooling events (such as the Northern Hemisphere, NH, warm Bølling-  
59 Allerød and the Southern Hemisphere, SH, Antarctic Cold Reversal, Andersen et al., 2004; Jouzel et al.,  
60 2007) may have influenced both hemispheres and triggered major continental hydro-climatic changes  
61 (e.g. Barker et al., 2011; Blard et al., 2011a, 2009; Broecker and Putnam, 2012; Jomelli et al., 2014;  
62 Martin et al., 2018; Placzek et al., 2006; Sylvestre et al., 1999). However, the respective  
63 interhemispheric impacts of oceanic and atmospheric changes remain controversial and the subject of  
64 various investigations (e.g. Blard et al., 2009; Fritz et al., 2007; Jomelli et al., 2014).

65           Because the tropics are intersectional between the Northern and Southern Hemispheres, this  
66 region is key to addressing the respective impacts of both hemispheres on global and regional climates  
67 (Jackson et al., 2019). The Tropical Andes, and particularly the Altiplano Basin, exhibit outstanding  
68 hydro-climatic archives of climatic changes during the last deglaciation. Indeed, the Antarctic Cold  
69 Reversal (a SH event) was reported to have exerted a major influence on glacial dynamics throughout  
70 the tropical and sub-tropical Andes (Jomelli et al., 2014). Furthermore, in the Altiplano, paleo-  
71 highstands of Lakes Tauca (52,000 km<sup>2</sup>) and Coipasa (32,000 km<sup>2</sup>) are synchronous with the second  
72 half of the Heinrich Stadial 1 (16.5 – 14.5 ka BP) and the Younger Dryas (12.9 – 11.7 ka BP),  
73 respectively (NH events, Blard et al., 2011a; Placzek et al., 2006; Sylvestre et al., 1999). These lake  
74 cycles are characterized by abrupt transgressions and regressions within 1 kyr, implying drastic and fast  
75 climatic changes that occurred synchronously with abrupt changes within the northern Atlantic region  
76 (Andersen et al., 2004; McManus et al., 2004). Throughout the Altiplano Basin, moraine records  
77 evidence glacial standstills or re-advances synchronous with the Lake Tauca highstand, which Martin  
78 et al. (2018) used to reconstruct the regional distribution of precipitation during Heinrich Stadial 1 (16.5  
79 – 14.5 ka BP), for which they computed a regional precipitation increase of 130% (i.e. a factor of 2.3).

80 Relying on their reconstructed spatial distribution of precipitation, they concluded that the change in  
81 rainfall regime during Heinrich Stadial 1 resulted from modifications of the South American Summer  
82 Monsoon (SASM), involving a southward shift of synoptic atmospheric features compared to the  
83 present.

84 Numerous studies have provided local chronologies of glaciers fluctuations in the tropical  
85 Andes for the last glacial maximum (LGM) and late-glacial period (e.g. Bromley et al., 2016; Carcaillet  
86 et al., 2013; Farber et al., 2005; Palacios et al., 2020; Shakun et al., 2015; Smith, 2005; Ward et al.,  
87 2015; Zech et al., 2009) and climatic reconstructions from glacial landforms in the vicinity of the  
88 Altiplano have already been reported (Jomelli et al., 2011; 2016, Kull et al., 2008; Kull and Grosjean,  
89 2000; Malone et al., 2015). In the Altiplano, Blard et al. (2009) and Placzek et al. (2013) quantified  
90 temperature variations based on joint lake- and glacier-budget calculations during the Lake Tauca cycle.  
91 However, these previous approaches suffered from substantial uncertainties on the spatial distribution  
92 of precipitation over the Altiplano because very few climatic reconstructions are available before and  
93 after the Lake Tauca highstand. Notably, little is known about Tropical Andean temperatures and  
94 precipitation during the LGM-Heinrich 1 transition, the ACR and the Younger Dryas. In this regard,  
95 climatic reconstructions spanning the last deglaciation in the High Tropical Andes are critical to  
96 establishing the extent and influence of these major and potentially opposing climatic changes recorded  
97 at high latitudes of the Northern and Southern Hemisphere.

98 Here we present new glacial chronologies from four sites of the Bolivian Altiplano: the Zongo  
99 valley (16.3°S, 68.1°W), Nevado Sajama (18.1°S, 68.9°W), Cerro Tunupa (19.8°S, 67.6°W), and Cerro  
100 Luxar (21.0°S, 68.0°W). These chronologies are based on cosmic ray exposure (CRE) dating of  
101 recessional moraine sequences and glacially abraded bedrock surfaces. These new data extend the  
102 existing chronologies of Smith et al. (2005), Jomelli et al. (2011), Blard et al. (2009, 2013) and Martin  
103 et al. (2018). Considering lake-level variations over the same period, we applied an inversion method  
104 that builds on our previous studies (Blard et al. 2009, Martin et al. 2018). By coupling glacier- and lake-  
105 budget calculations, we took advantage of their contrasting sensitivities to temperature and precipitation,  
106 and reconstructed temperature and precipitation ranges that jointly satisfy glacial and lacustrine extents  
107 for a given moment of the last deglaciation.

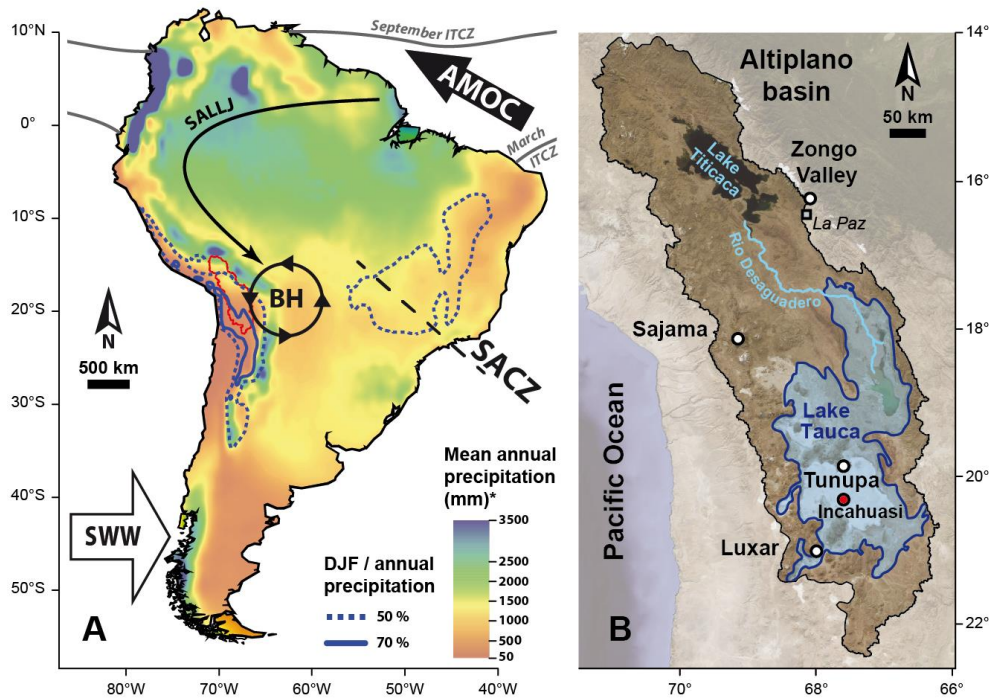

## 108 **2. Geological Setting**

### 109 **2.1. Climate of the Altiplano**

110 The Altiplano is a wide intra-mountain plateau covering an area of 196,000 km<sup>2</sup> and bounded  
111 by the eastern and western Andes Cordilleras (Fig. 1). Due to its regional topography, this area is an  
112 endorheic basin (hereafter, the “Altiplano Basin”). This basin extends from 15.5°S (Peru) to 22.5°S  
113 (Bolivia), and ranges in elevation from 3,658 m above sea level (asl) at Salar de Uyuni to 6,542 m asl  
114 at Sajama volcano.

115 The precipitation regime of the Altiplano is under the climatic influence of the SASM, which  
116 brings most of the annual rainfall during the austral summer (December, January, February, Vera et al.,  
117 2006; Zhou and Lau, 1998). During this period, the dry westerlies are weakened by subtropical jet  
118 modulations and a concomitant southward expansion of the tropical easterlies. This modification  
119 promotes the transport of humidity from the Amazonian basin and central Brazil towards the Altiplano  
120 (Garreaud et al., 2003, 2009; Segura et al., 2019; Vuille, 1999; Vuille and Keimig, 2004). The  
121 orographic effect of the Eastern Cordillera modulates this transport and creates an important  
122 precipitation gradient over the Altiplano. Annual rainfall presently ranges from 800 mm on the shores  
123 of Lake Titicaca to 60 mm in the vicinity of the Laguna Colorada, southwest Bolivia (Fig. 1).

124 Present temperatures are relatively uniform over the Altiplano, and the daily temperature  
125 variability is larger than the seasonal variability (Aceituno, 1996) as is often observed in the tropics  
126 (Hastenrath, 1991). Maximum daily temperatures occur around 2 pm LT when solar radiation is  
127 maximal. For most of the year, daily temperature variations are constrained by night radiative loss from  
128 the surface. Therefore, the daily amplitude of temperature variations is reduced during the wet season  
129 when cloudiness is important (Condom, 2002). Climatic conditions at the glacial sites are presented in  
130 Table 1.

131

 137 *December–February (DJF) to annual precipitation ratio. Precipitation data are mean values during*  
 138 *1979–2016 from ERA-Interim (Dee et al., 2011). (B) The Altiplano Basin and the locations of sites*  
 139 *analyzed herein overlaid on SPOT Imagery. White dots indicate glacial valleys, and the red dot indicates*  
 140 *lacustrine deposits sampled and analyzed herein. The maximum paleo-extent of Lake Tauca is shaded*  
 141 *in blue. The black line delimits the Altiplano endorheic basin.*

## 142 2.2. Altiplano hydrology and paleolake records

143 The Altiplano endorheic basin comprises a north-south succession of four adjacent sub-basins  
 144 (Fig. 2). The Titicaca watershed in the northern Altiplano is the highest (lake altitude, 3,812 m asl) and  
 145 wettest sub-basin. It drains to the southeast via Rio Desaguadero (Figs. 1 and 2) to the Poopo watershed.  
 146 Lake Poopo was a shallow lake (<3 m deep) that vanished in 2015 due to ongoing climate change and  
 147 excessive irrigation (Satgé et al., 2017). The small Coipasa watershed is to the southwest of Poopo  
 148 watershed, and the two are separated by an elevation threshold of 3,703 m asl (Fig. 2). The Uyuni  
 149 watershed (bottom at 3,660 m asl) is to the south of Coipasa watershed, from which it is separated by  
 150 an elevation threshold of 3,672 m asl. Channels and paleochannels between the different basins indicate  
 151 that they were hydrologically connected during wetter periods.

152

153 *Figure 2. Topographic cross section of the Altiplano showing the hydrological relationships between*  
 154 *lake and salar watersheds (modified from Argollo and Mourguiart, 2000). The threshold between the*  
 155 *Poopo and Coipasa watersheds is 3,703 m asl. The threshold between the Coipasa and Uyuni*  
 156 *watersheds is 3,672 m asl. The elevation reported for paleolake Coipasa is based on our new shoreline*  
 157 *<sup>14</sup>C ages (see Section 4.1.1).*

158

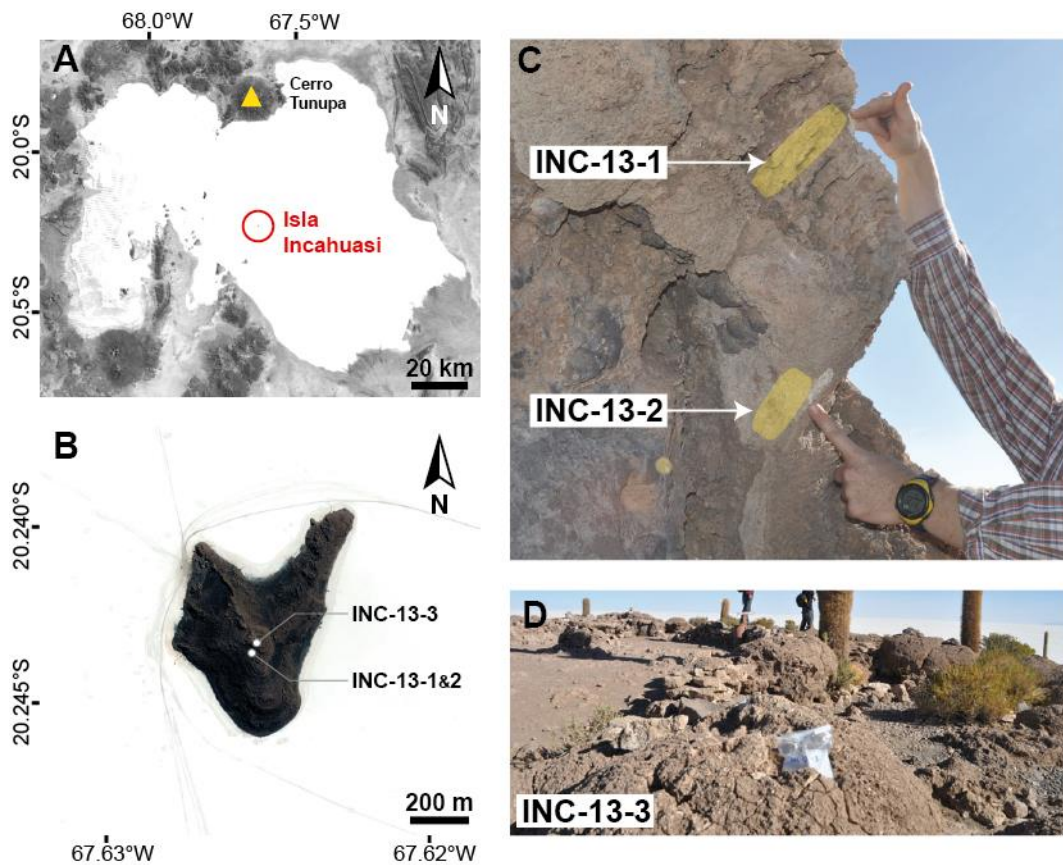

159 The three southernmost basins of the Altiplano are dry at present, but were covered by large  
 160 lakes during the wettest periods of the Quaternary (Placzek et al., 2006; Sylvestre et al., 1999). Of the  
 161 several lake episodes that occurred during the last 120 kyr, the Lake Tauca episode was the widest and  
 162 deepest (~110 to 120 m deep, Placzek et al., 2006; Blard et al., 2011). During the Lake Tauca highstand  
 163 (3,770 m asl), the lake extent covered the totality of the three southernmost basins (Poopo, Coipasa and  
 164 Uyuni; Figs. 1 and 2).

165 U-Th and <sup>14</sup>C dating of its shorelines constrain the timing of the Lake Tauca cycle, i.e. the  
 166 transgression (18-16.5 ka BP), highstand (16.5-15.5 ka BP) and regression phases (14.5-13.5 ka BP,  
 167 Blard et al., 2013a). During its highstand, the lake level reached a maximum altitude of 3,770 m asl and  
 168 covered 52,000 km<sup>2</sup>. The Coipasa Lake cycle is characterized by a transgression from 13.3 to 12.9 ka  
 169 BP, a highstand from 12.9 to 11.8 ka BP and a regression from 11.8 to 10.2 ka BP (Blard et al., 2011a;  
 170 Placzek et al., 2006; Sylvestre et al., 1999). Placzek et al. (2013) reported that the highstand lake level  
 171 reached 3,700 m asl, covering 28 400 km<sup>2</sup>.

172 To expand the existing age dataset, we sampled two new bioherms on Isla Incahuasi (20.24°S -  
 173 67.62°W, Table 2), a rocky hill in the center of Salar de Uyuni (Fig. 3). The first bioherm lies 5 m below  
 174 the top of the hill (3,715 masl). Dislocations in the calcareous crust revealed a radial cross section of its  
 175 cortical structure. We took advantage of this exposure and sampled the outermost cortex (INC-13-1),  
 176 which presents a fine radial branching structure, and a more inner region of the bioherm (INC-13-2),

177 exhibiting a massive algal facies with no visible laminations. The second bioherm is located atop the  
178 hill (3,720 m asl), and we sampled the outermost cortex (INC-13-3).

179

### 185 2.3. Moraine Settings

186 The four paleoglaciaded sites presented in this study span the latitudinal range from 16.3°S to  
187 21.0°S (Fig. 1).

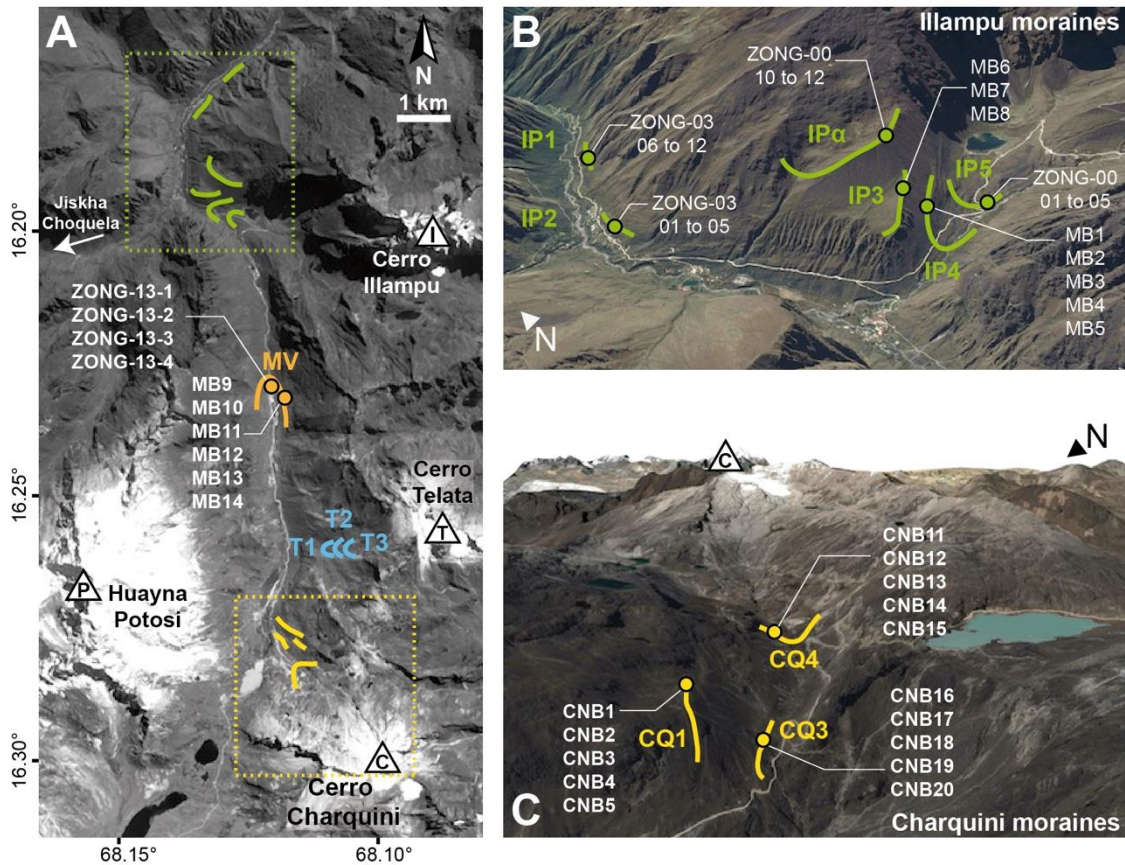

#### 188 2.3.1. Zongo Valley (16.2°S - 68.1°W)

189 Zongo valley is in the Cordillera Real in the northern part of the Bolivian Altiplano (Fig. 1). It  
190 is a northward-orientated valley, draining a mountainous area of about 150 km<sup>2</sup> towards the Amazonian  
191 basin and culminating at Huayna Potosi (6,088 m asl). Presently glaciaded areas have small extents.  
192 Huayna Potosi presently bears a retreating slope glacier on its southern face which has been monitored  
193 by the IRD-GREAT ICE team since 1991 (Rabatel et al., 2013; Soruco et al., 2009). Other summits in

194 the valley (Telata, Charquini) only bear small glaciers or perennial snow patches. The valley exhibits  
195 geomorphic evidence of important past glaciations including several moraines and roches moutonnées.  
196 This part of the Cordillera Real massif mainly comprises granitic rocks. The glacial geomorphic features  
197 of Zongo Valley are thus suitable for CRE dating by measuring  $^{10}\text{Be}$  in quartz. Such data have already  
198 been reported for this valley (Jomelli et al., 2011; Martin et al., 2018; Smith et al., 2005). We sampled  
199 23 new moraine boulders and combined our and previous results to better constrain the timing of the  
200 deglaciation in the valley (Fig. 4, Table 3).

201 The different moraines are classified into four groups. The Cerro Illampu group (green moraines  
202 on Fig. 4) includes the five most distal moraines (IP1 to 5) and a perched frontal moraine left by a small  
203 glacier of local origin (IP $\alpha$ ). Moraines IP1 to 5 are LGM moraines studied by Smith et al. (2005) and  
204 Martin et al. (2018). Downstream from these moraines, glacial morphologies vanish and the U-shaped  
205 valley gradually becomes V-shaped, indicating the former extent of past glacial activities. IP1 to 3 are  
206 lateral moraines and IP4 and 5 are frontal moraines in the bottom of the valley. Due to their distal  
207 position in the valley, the former ice tongues associated with moraines IP1 to 3 resulted from the  
208 convergence of 5 ice streams flowing down from Huayna Potosi, Charquini, Telata, Cerro Illampu and  
209 Jiskha Choquela (Fig. 4A). The IP 4 and 5 ice tongues flowed from the Cerro Illampu summit alone.

210 The Main Valley (MV) moraine gathers a complex of small recessional (lateral and frontal)  
211 moraines that lie upstream within a portion of the Zongo valley that flows straight north (Fig. 4A). The  
212 associated ice tongue resulted from the convergence of ice flows from Huayna Potosi, Cerro Charquini  
213 and Cerro Telata. The T1 to T3 moraines are associated with ice flows downstream from Cerro Telata.  
214 These sets of frontal moraines were dated to the Pleistocene - Holocene transition by Jomelli et al.  
215 (2011). CQ1 and CQ3 are lateral moraines and CQ4 is a frontal moraine. Whereas the ice tongue  
216 associated with CQ1 must have resulted from the convergence of ice streams from Huayna Potosi and  
217 Charquini, CQ3 and CQ4 are only associated with downstream ice flows from Cerro Charquini. The  
218 MV and CQ moraines were sampled for the present study (see Table 3). From IP1 to CQ4, the glacial  
219 record spans over 15 km horizontally and over 1200 m vertically. Examples of collected samples are  
220 shown on Fig. 5.

221  
 222 *Figure 4. Moraine samples in Zongo Valley. (A) Overview of moraine groups and samples. (B) Cerro*  
 223 *Illampu moraines (sample numbers from Smith et al., 2005 and Martin et al., 2018). (C) Charquini*  
 224 *moraines. Sample names in bold font are original samples from this study (MV and CQ groups). Samples*  
 225 *from the T moraine group (blue) are from Jomelli et al. (2011), and are not detailed here (see Table 3).*

226  
 227 *Figure 5. Examples of sampled boulders in Zongo Valley. Samples shown here belong to the CQ1*  
 228 *(CNB1, 3, and 4) and MV (MB12) moraines.*

229

2.3.2. Nevado Sajama (18.1°S - 68.9°W)

230

Nevado Sajama is an andesitic and rhyodacitic stratovolcano in the western part of the central

231

Altiplano, and the highest summit of Bolivia (6,542 m asl). Nevado Sajama presently bears a small ice

232

cap of ~5 km<sup>2</sup> spanning 5,500–6,500 m asl. Larger past glacial activities carved numerous glacial valleys

233

into the flanks of the volcano radiating from the summit. We collected 18 samples on four moraines and

234

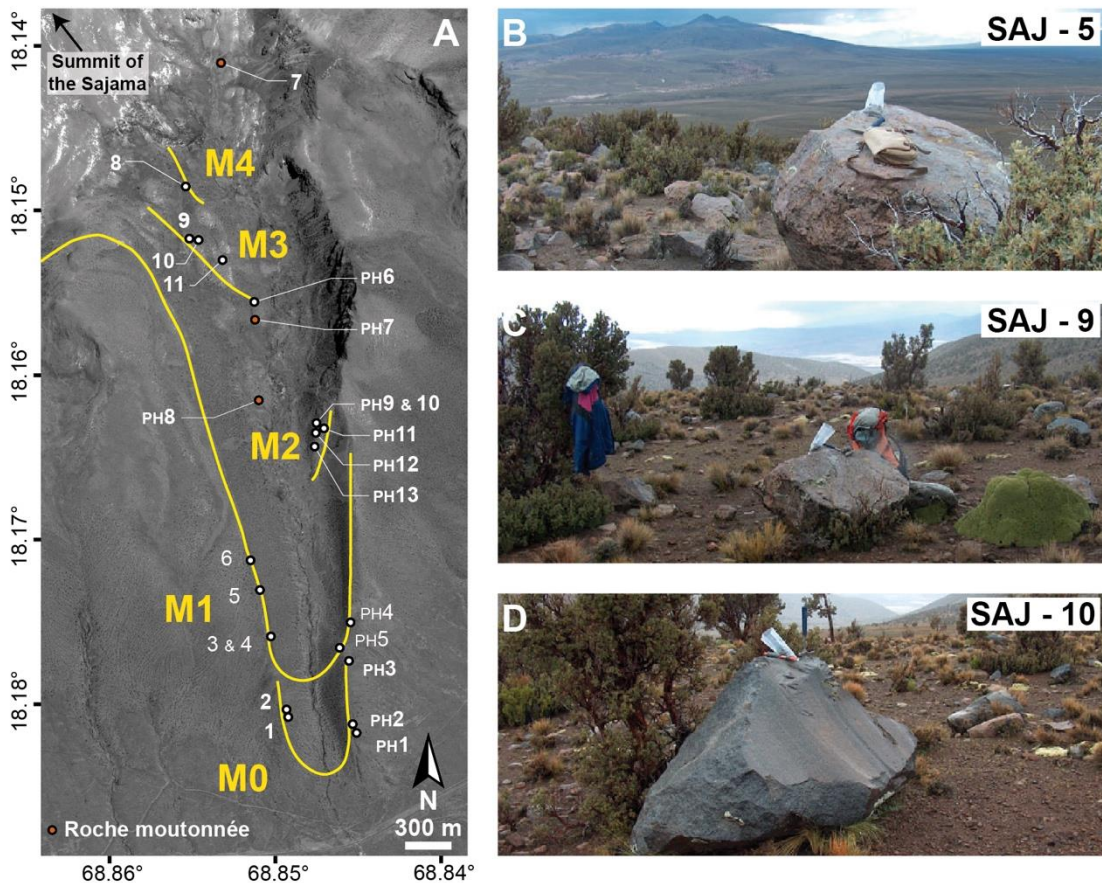

three roches moutonnées in the main southward valley of Nevado Sajama, where a former glacier left a

235

prominent moraine and smaller cordons (Fig. 6). The M1 moraine was CRE dated (<sup>3</sup>He in pyroxenes)

236

at 15.1 ± 1.1 ka BP by Martin et al. (2018).

237

238 *Figure 6. Moraine and roche moutonnée samples in the main southward valley of Nevado Sajama. (A)*

239

*Detailed samplings of each moraine. White and orange dots indicate morainic boulder and roches*

240

*moutonnées samples, respectively. Solid yellow lines delimit the moraines in the main scope of this*

241

*study. Full sample names include the prefix 'SAJ-'. Only samples listed in bold font are from this study*

242

*(i.e. all samples except those from M1, which are from Martin et al., 2018). (B–D) Representative*

243

*morainic boulder samples.*

244

Terminal moraine M0 was formed by the maximal ice extent in the valley, and M1–4 are

246

recessional moraines deposited subsequently. These moraines lie in the bottom part of the valley,

247

towards the southwest. The terminus of M1 is 700 m upstream from that of M0 (horizontal distance);

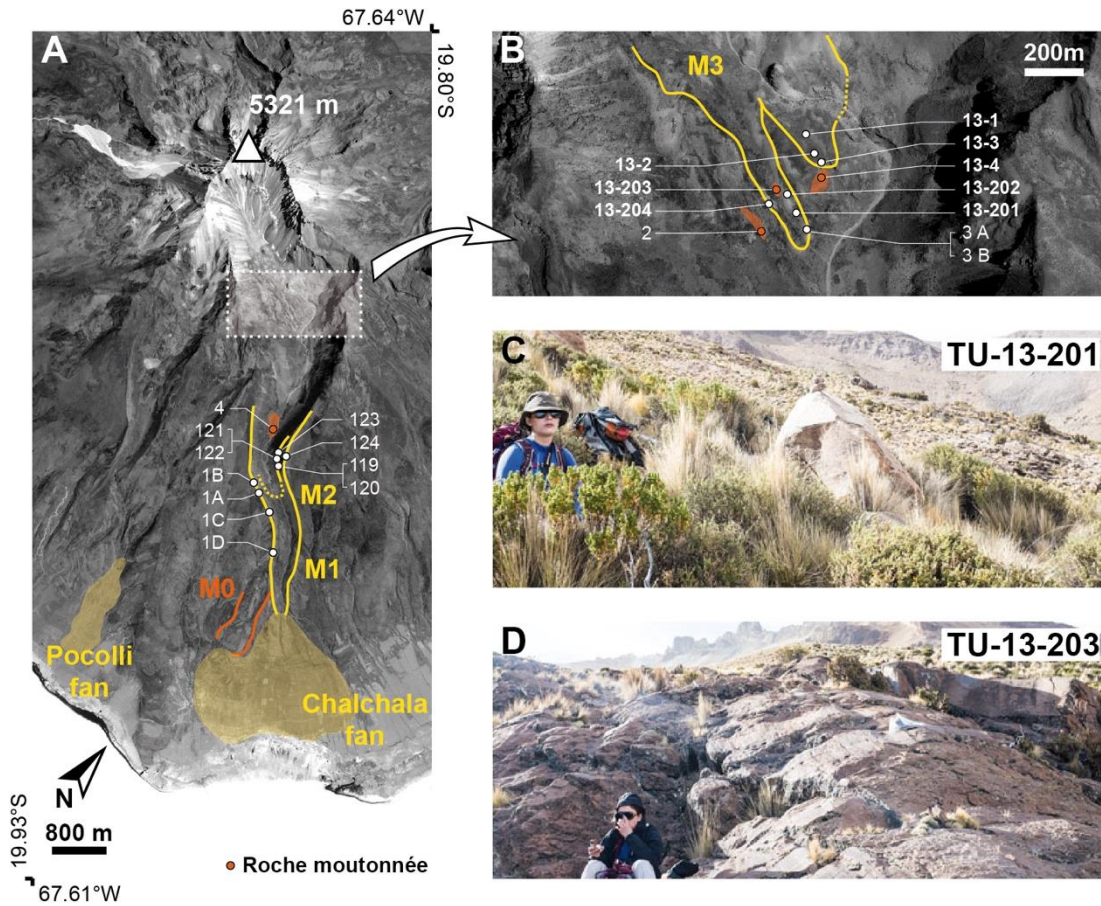

248 M1 is more sharp-crested than M0 and was built laterally atop M0 lateral moraines. Recessional  
249 moraines M2 and M3 are probably associated with short standstills as they are much smaller than M1.  
250 Additionally, the geometry of M3 suggests a narrower ice flow associated with a reduced upstream  
251 accumulation area (Fig. 6). Two roches moutonnées were sampled between M2 and M3 (SAJ-PH7 and  
252 SAJ-PH8) and another upstream of M4 (SAJ-7). This glacial record spans over 5 km horizontally and  
253 over 300 m vertically. The andesitic composition of the samples led us to establish CRE ages from in-  
254 situ cosmogenic  $^3\text{He}$  concentrations in pyroxenes. CRE  $^{36}\text{Cl}$  ages reported by Smith et al. (2009) for the  
255 eastward valleys of Nevado Sajama indicate late-glacial and Holocene moraines. Scatter among their  
256 samples from the late-glacial period precludes a precise chronology.

### 257 *2.3.3. Cerro Tunupa (19.8°S - 67.6°W)*

258 Cerro Tunupa (summit elevation, 5,321 m asl) is an andesitic stratovolcano in the center of the  
259 southern Altiplano, above the northern edge of Salar de Uyuni. Cerro Tunupa does not presently bear  
260 permanent ice cover, although numerous glacial landforms are preserved in its southern flank (Blard et  
261 al., 2009; Clayton and Clapperton, 1997). Chalchala valley is the main glacial valley, extending from  
262 the glacial cirque towards the southeast. Downstream, the glacial carving gradually disappears and the  
263 valley widens on the Chalchala glacial fan (Fig. 7). In this valley, Blard et al. (2009, 2013a) studied four  
264 moraines (M0–3) and the Chalchala fan delta (Fig. 7). M0 is a pre-LGM moraine outlet cross-cut by  
265 moraine M1. M1 and M2 have cosmogenic  $^3\text{He}$  exposure ages contemporaneous with the Lake Tauca  
266 highstand (Blard et al., 2009, 2013a). Martin et al. (2018) recalculated the age of M2 to be  $15.7 \pm 0.6$   
267 ka BP based on the data of Blard et al. (2009) and additional Bayesian conditions based on the upper-  
268 lying roche moutonnées TU-2 and TU-4. The recession indicated by M3 was dated to 14.5 ka BP by  
269 Blard et al. (2009, 2013).

270 As shown on Fig. 7, the lateral part of M2 was sampled but evidence of its frontal part remains  
271 unclear. The M3 moraine complex corresponds to small ice tongues that stood as the downstream  
272 digitations of a small-extent cirque glacier. A complete description of the Chalchala moraines is  
273 available in Blard et al. (2009). Samples from the Chalchala valley span over 400 m vertically and 4 km  
274 horizontally.

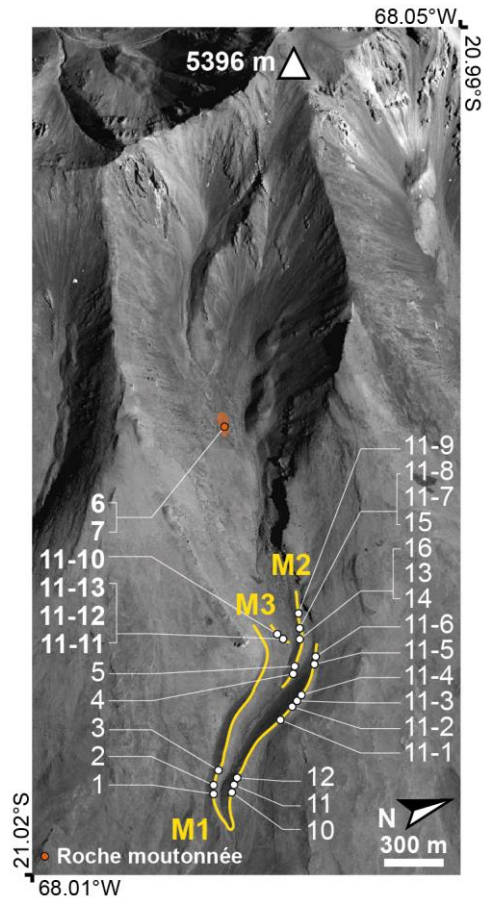

275 In this study, we completed the sampling of the M3 moraine complex. We sampled two new  
 276 roches moutonnées and six new morainic boulders (sample names including “13”). These samples were  
 277 collected for CRE age determinations from in-situ  $^3\text{He}$  concentrations in pyroxenes.

278  
 279

 281 *glacial valley. White and orange dots indicate morainic boulder and roches moutonnées samples,*  
 282 *respectively. Solid yellow lines delimit the moraines in the main scope of this study. (B) Enlarged view*  
 283 *of the upstream samples associated with the M3 morainic complex. (C) The TU-13-201 moraine*  
 284 *boulder. (D) The TU-13-203 roche moutonnée. Full sample names include the prefix ‘TU-’. Only*  
 285 *samples labelled in bold font are from this study (samples including “13-” in (B)); other samples were*  
 286 *presented in Blard et al. (2009, 2013a).*

287                                    *2.3.4. Cerro Luxar (21.0°S - 68.0°W)*

288                                    Cerro Luxar is an andesitic stratovolcano in the southwestern Altiplano, 70 km south of Salar  
289 de Uyuni; it belongs to a wide volcanic province extending from the western Cordillera to the center of  
290 the Altiplano. Cerro Luxar does not currently have permanent ice cover, but numerous glacial  
291 geomorphic features are observed in the valleys carved into its flanks. Because of the andesitic  
292 composition of the Luxar volcano, in-situ cosmogenic <sup>3</sup>He concentrations in pyroxenes can be used to  
293 date the glacial features. The M1 moraine (Fig. 8) is the terminal moraine, corresponding to the last  
294 maximal extent of the ice tongue; it is a sharp-crested moraine extending continuously over more than  
295 1 km and delimiting a narrow and sinuous ice tongue. The M2 and M3 moraines are recessional  
296 moraines located upstream in the valley. M2 extends over 500 m on the left bank and over 200 m on the  
297 right bank. Martin et al. (2018) measured exposure ages on morainic boulders of moraines M1 and M2  
298 (Fig. 8) and dated them at  $16.6 \pm 0.7$  ka BP and  $15.4 \pm 0.9$  ka BP, respectively. Here we extend their  
299 results with two samples on boulders of moraine M3 (sampled on the more prominent right bank) and  
300 two upper-lying roches moutonnées (located upstream of the three moraines, in the glacial cirque).  
301 Combined with the samples of Martin et al. (2018), this glacial landform record spans 1.2 km  
302 horizontally and 450 m vertically.

303

## 309 **3. Methods**

### 310 **3.1. CRE dating methods**

#### 311 *3.1.1. Sampling methods*

312 Boulders were sampled using a hammer and a chisel. We favored large angular boulders to  
313 minimize the possibility of recent surface deflation of the diamict matrix. For both boulders and roches  
314 moutonnées, the thicknesses of the samples ranged between 2 and 5 cm (Tables 3–6). The tops of many  
315 boulders presented flat or slightly sloping surfaces, generally smooth and clean without any evidence of  
316 exfoliation or physical weathering. This suggests that they have experienced only negligible denudation  
317 (i.e. less than a few mm) since their deposition.

#### 318 *3.1.2. In-situ <sup>10</sup>Be concentration measurement*

319 To measure cosmogenic <sup>10</sup>Be concentrations in quartz mineral fractions, samples were prepared  
320 at the CRPG (Nancy, France) to obtain pure BeO targets for subsequent <sup>10</sup>Be/<sup>9</sup>Be isotopic analysis.  
321 Samples were first crushed and wet-sieved to collect the 200–800 μm fraction. Quartz grains were  
322 magnetically and electrostatically separated, then isolated through selective dissolution in a concentrated  
323 H<sub>2</sub>SiF<sub>6</sub>-HCl solution. Once pure quartz was obtained, 30% of the mass of each sample was dissolved  
324 during three successive HF leaching steps in order to remove any atmospheric <sup>10</sup>Be contamination from  
325 the quartz. We then added 150–300 mg of an in-house <sup>9</sup>Be carrier (2,020 ppm <sup>9</sup>Be) to the samples and  
326 completely dissolved them in concentrated HF. To isolate beryllium, samples were fractionated in three  
327 alkaline precipitations alternating with two separations on ionic-exchange columns and a final  
328 dehydration at 700 °C.

329 The resulting BeO was mixed with niobium powder, introduced into a copper cathode, and  
330 pressed. The <sup>10</sup>Be/<sup>9</sup>Be ratios were analyzed by accelerator mass spectrometry at the French national  
331 facility ASTER (LN2C, CEREGE, Aix-en-Provence, France). During each analytical session, the  
332 measured <sup>10</sup>Be/<sup>9</sup>Be ratios were normalized to the <sup>10</sup>Be/<sup>9</sup>Be ratio of the NIST SRM 4325 reference  
333 material (<sup>10</sup>Be/<sup>9</sup>Be = (2.79 ± 0.03) × 10<sup>-11</sup>; Nishiizumi et al., 2007). During the three analytical sessions,

334 blank values were  $(2.7 \pm 1.7) \times 10^{-15}$ ,  $(1.5 \pm 0.4) \times 10^{-15}$  and  $3.9 \times 10^{-15}$ , respectively, yielding respective  
335 maximum blank corrections of sample  $^{10}\text{Be}/^9\text{Be}$  ratios of 6%, 3%, and 3%.

### 336 *3.1.3. In-situ $^3\text{He}$ concentration measurements*

337 For cosmogenic  $^3\text{He}$  measurements, all samples were prepared and analyzed at the CRPG.  
338 Samples were crushed and wet-sieved to collect the 180–800  $\mu\text{m}$  fraction. We concentrated heavy  
339 minerals by density separation in sodium polytungstate solutions ( $d \sim 3.1 \text{ g cm}^{-3}$ ) and rinsed them with  
340 deionized water. Black and green pyroxenes were observed and identified by scanning electron  
341 microscopy, then mono-mineral grains without any adhering lava were handpicked under a binocular  
342 microscope and packed into stain capsules. The prepared pyroxene aliquots weighed between 11.4 and  
343 57.2 mg.

344 The total  $^3\text{He}$  concentrations of the samples were measured by split flight tube mass  
345 spectrometry following a previously established procedure (Blard et al., 2015; Mabry et al., 2012;  
346 Zimmermann et al., 2012) summarized here. Pyroxene aliquots were fused in a single vacuum resistance  
347 furnace during 15 min at 1400–1500  $^{\circ}\text{C}$ . The extracted gas was purified using activated carbons, getters,  
348 and a cryogenic pump, and  $^3\text{He}$  and  $^4\text{He}$  concentrations were analyzed in the spectrometer. Furnace  
349 blanks induced a mean correction of  $4 \pm 3\%$  (with a maximal value of 12%). The sensitivity of the mass  
350 spectrometer was calibrated using the HESJ standard (Matsuda et al., 2002) as described in Blard et al.  
351 (2013a) over a range of helium pressures that encompassed those of the measured samples, and from  
352 which the adequate sensitivity could be interpolated. Mean  $1\sigma$  external reproducibilities for  $^3\text{He}$  and  $^4\text{He}$   
353 of  $2.0 \pm 0.6\%$  and  $1.9 \pm 2.3\%$ , respectively, with respective maximum values of 3.1% and 7.0%. During  
354 each analytical session, we measured CRONUS-P pyroxene standard aliquots, which yielded a mean  
355 concentration of  $(4.92 \pm 0.16) \times 10^9 \text{ at g}^{-1}$ , in agreement with the mean reported value of  $(5.02 \pm 0.06)$   
356  $\times 10^9 \text{ at g}^{-1}$  (Blard et al., 2015).

357 Blard et al. (2013a, 2014) measured magmatic  $^3\text{He}$  concentrations in pyroxenes from Cerro  
358 Tunupa and Cerro Uturuncu via prolonged vacuum step-crushing. They showed that magmatic  $^3\text{He}$   
359 concentrations were 2–3 orders of magnitude below cosmogenic  $^3\text{He}$  concentrations in volcanic

360 formations of the Altiplano. Relying on their data, we derived and applied a magmatic  $^3\text{He}$  correction  
361 of  $8.50 \times 10^4$  at  $\text{g}^{-1}$  to all our samples,

362 Nucleogenic  $^3\text{He}$  concentrations were calculated from the major and trace element compositions  
363 of both lavas and phenocrysts, as in Blard et al. (2013a) (measurements performed by SARM-CNRS).  
364 We calculated both (U-Th-Sm)/ $^4\text{He}$  eruption ages and nucleogenic  $^3\text{He}$  production rates (following  
365 Andrews and Kay, 1982 and Andrews, 1985) to derive  $^3\text{He}$  nucleogenic concentrations. For each  
366 sample, the final cosmogenic  $^3\text{He}$  concentration was obtained by subtracting the magmatic and  
367 nucleogenic components from the total  $^3\text{He}$  concentration. These corrections represent less than 3% of  
368 the total measured  $^3\text{He}$  concentrations in all samples.

#### 369 *3.1.4. Cosmogenic exposure age computation*

370 Because the cosmogenic production rate is a pivotal parameter in the calculation of exposure  
371 ages, we relied on the weighted means of local calibration values (detailed below). This approach has  
372 two advantages: (i) local calibration values limit potential inaccuracies arising from the spatial scaling  
373 procedure (Martin et al., 2015), and (ii) the use of more than one calibration study makes the final  
374 calibration value used in the age calculations more robust. The Sea Level High Latitude (SLHL)  
375 production rate used to calculate the  $^{10}\text{Be}$  CRE ages is the weighted mean of the production rates of  
376 Blard et al. (2013a), Kelly et al. (2015), and Martin et al. (2015); these production rates were obtained  
377 in the High Tropical Andes from calibration sites within limited distances from the glacial landforms  
378 dated in the present study (all are within the Altiplano Basin, except that of Kelly et al., 2015, which is  
379 30 km away). Similarly,  $^3\text{He}$  CRE ages were calculated using the weighted mean of the production rates  
380 of Blard et al. (2013b, within the basin) and Delunel et al. (2016, 60 km away). We took the uncertainties  
381 of both production rates as the weighted standard deviations (Martin et al., 2017) taken over the  
382 individual production rate values and propagated it in the computed ages.

383 CRE computations were performed using the online CREp calculator (Martin et al., 2017) and  
384 the modified Lal (1991) time-dependent scaling scheme (Balco et al., 2008; Stone, 2000) with the ERA-  
385 40 spatialized atmosphere (Uppala et al., 2005) and the virtual dipolar moment (VDM) reconstruction  
386 of Muscheler et al. (2005). Borchers et al. (2016) showed that the modified Lal model and the LSD

387 model (Lifton et al., 2014) were the most efficient models available to reduce discrepancies between the  
388 different calibration studies at SLHL conditions. Martin et al. (2015) similarly showed that the modified  
389 Lal scheme performs better in the High Tropical Andes, especially when combined with the ERA-40  
390 atmosphere and the VDM reconstruction of Muscheler et al. (2005).

### 391 *3.1.5. Bayesian filtering of CRE ages from stratigraphic relationships*

392 For each moraine in this study, we computed a normalized sum of the probability density  
393 function (PDF) of the age of each sample and applied a Bayesian age filtering. Stratigraphic relations  
394 between moraines and roches moutonnées bring additional time constraints to the objects that they  
395 bracket. These can be formulated in terms of Bayesian conditions (conditional probability) to produce  
396 or refine age probability densities associated with moraines (Parnell et al., 2011). We used the approach  
397 of Blard et al. (2013b) and Martin et al. (2015) on some of the studied moraines to refine their age  
398 distributions and limit the influence of possible outliers on the final results. We consider  $f_{\text{Object}}$  as the  
399 non-filtered initial PDF of the dated object (a function of time  $t$ ). Stratigraphic observations enable the  
400 identification of an older and a younger object, each associated with its own PDF ( $f_{\text{OlderObject}}$  and  
401  $f_{\text{YoungerObject}}$ , respectively). A new filtered PDF  $f^*_{\text{Object}}$  can then be recalculated as:

$$402 \quad f^*_{\text{Object}}(t) = f_{\text{Object}}(t) \times \int_t^{\infty} f_{\text{OlderObject}}(\tau) d\tau \times \int_0^t f_{\text{YoungerObject}}(\tau) d\tau \quad (1)$$

403 If no measurements are available for the object of interest, or if scatter is too important, a PDF can be  
404 derived for the bracketed object by replacing  $f_{\text{Object}}$  by 1.

405 We systematically used this approach to filter and refine the age distributions of the moraines  
406 in this study. For each moraine, a raw PDF was first established as the normalized sum of the PDF of  
407 each sample of that moraine. Then, we used Bayesian conditions based on the raw PDFs of older and  
408 younger objects to bracket the age to be refined. This was not possible for the oldest and youngest  
409 objects at a given site, which only benefited from one Bayesian condition (based on the second oldest  
410 or second youngest objects, respectively). This framework was adjusted for special cases exhibiting  
411 particularly large scatter among the individual ages associated with the central or bracketing objects.

412 When the age of the older/younger object was characterized by significant scatter, it was replaced by  
413 the object immediately older/younger than itself. When the central object to be refined presented  
414 scattered ages older and/or younger than those of the bracketing objects, but the bracketing PDFs were  
415 available, we replaced  $f_{\text{Object}}$  by 1. Final moraine ages were determined using the median and  $1\sigma$ -range  
416 of the thusly-refined moraine PDFs. For simplicity, the uncertainty associated with each moraine age is  
417 the mean of the left and right  $1\sigma$  distances to the median. Illustration of the Bayesian processing on age  
418 data is illustrated on Fig. S6 (Supplementary Information).

### 419 **3.2. Equilibrium line altitude calculation methods**

420 At the equilibrium line altitude (ELA) of a glacier, the glacier's mean annual mass balance is  
421 null. Because ELA is an integrative signal of the climatic conditions driving glacial dynamics (Ohmura  
422 et al., 1992), paleo-ELAs have been extensively used over the past 40 years for climate reconstructions  
423 (Loibl et al., 2014; Porter, 2000; Sissons and Sutherland, 1976; Stauch and Lehmkuhl, 2010). Several  
424 methods have been reported and compared to infer paleo-ELAs from the geomorphic features of glacial  
425 valleys (Benn et al., 2005; Benn and Lehmkuhl, 2000; Meierding, 1982). These methods rely on  
426 different observations, such as the glacial cirque altitude, the maximum elevation of lateral moraines,  
427 the terminus altitude, or the hypsometry of the valley, and require variable amounts of knowledge about  
428 past glacial extents. Here we used the accumulation area ratio (AAR) method, which enables ELA  
429 determination for several glacial standstills in the same valley. This method does not require any balance  
430 ratio or index, and is thus less precise than the balance ratio or area altitude balance ratio methods  
431 (Osmaston, 2005). However, because the AAR method accounts for the surfaces of the ablation and  
432 accumulation zones, it is a more explicit reference to the surface glacier mass balance than the widely  
433 used toe-to-summit and toe-to-headwall altitude ratios (Benn and Lehmkuhl, 2000; Osmaston, 2005).  
434 The AAR method has been applied to derive accurate ELA values in various mountain glacier settings  
435 (e.g. Martin et al., 2018).

436 ELA determinations using the AAR method rely on the use of an appropriate AAR parameter,  
437 which ranges between 0.5 and 0.8 for present glaciers around the world (see Benn and Lehmkuhl, 2000,  
438 and Benn et al., 2005, for reviews). Here, we used AAR values based on mass balance measurements

439 conducted on three Andean glaciers by the GLACIOCLIM-IRD National Observation Service (Rabatel  
440 et al., 2013; Soruco et al., 2009). Observed present-day AAR values were regressed against annual mass  
441 balance measurements to account for the non-equilibrium conditions that characterize most  
442 glaciological years over the last three decades in the Andes. We established AAR values for this study  
443 as the  $y$ -intercepts of these regressions (i.e. the AAR for a null mass balance, see supplementary material  
444 of Martin et al., 2018, for details). Thus, we used an AAR range of 0.63–0.73 (average 0.68), consistent  
445 with Martin et al. (2018), to account for uncertainties (see review of AAR variability in Benn and  
446 Lehmkuhl, 2000). Required hypsometry data were derived from the NASA-USGS SRTM 1-arcsecond  
447 global digital elevation model (DEM).

### 448 **3.3. Climatic inversion methods**

#### 449 *3.3.1. Glacial extent and climatic conditions*

450 Climate controls glacial dynamics through accumulation (snowfall) and ablation (mainly  
451 melting and sublimation). Glaciers, and, more precisely, the past glacial extent indicated by moraine  
452 records, have thus been used as proxies of past climatic changes. Sagredo and Lowell (2012) proposed  
453 a complete climatic setting for Andean glaciers. They proposed classifying glaciers into different groups  
454 characterized by common climate settings. The glacial records presented in this study span two groups,  
455 the Cordillera Real and the southeast Altiplano, both characterized by cold and homogenous  
456 temperatures throughout the year and low precipitation inputs during the Austral summer (see Section  
457 1). The main difference between these two groups is annual rainfall, with the Cordillera Real receiving  
458 more precipitation than the southeast Altiplano (700 vs. 300 mm yr<sup>-1</sup>). In the southern Altiplano,  
459 although their summits stand above the 0 °C isotherm during the ablation season, volcanoes such as  
460 Cerro Tunupa (5,321 m asl) and Cerro Luxar (5,396 m asl) do not presently have permanent ice cover  
461 due to the low annual precipitation. This primary dependence of glacial dynamics on precipitation makes  
462 the region *precipitation-limited* (Ammann et al., 2001; Kull et al., 2008).

463 Considering the characteristic response time of several decades for mountain glaciers (Leclercq  
464 et al., 2014), we consider them to be in equilibrium with climatic conditions for our reconstructions.  
465 Therefore, we followed Martin et al. (2018, methodological comparison and discussion provided in their

466 Supplementary Information) and used empirical relations between ELA and the present climate derived  
467 from statistical analyses of modern glaciers. These relations consider that the ELA position depends  
468 primarily on mean temperature and precipitation values; enhanced accumulation concomitant with  
469 lowering of the ELA is associated with decreased temperature and/or increased precipitation, whereas  
470 the opposite trend is associated with raising of the ELA (Condom et al., 2007; Kuhn, 1989; Ohmura et  
471 al., 1992; Seltzer, 1994). For the Central Andes, Condom et al. (2007) extended the work of Fox (1993)  
472 to derive ELA (m asl) as:

$$473 \quad ELA = 3427 - 1148 \times \log_{10}(P) + \frac{T(z)}{LR} + z \quad (2)$$

474 where  $P$  is the annual rainfall (mm),  $T$  is mean annual temperature ( $^{\circ}\text{C}$ ),  $LR$  is the atmospheric lapse rate  
475 ( $^{\circ}\text{C m}^{-1}$ ), and  $z$  is the altitude of the temperature measurement (m asl). As in Martin et al. (2018), we  
476 chose this modeling approach for several reasons: (i) Equation (2) directly links ELA to the investigated  
477 climatic variables; (ii) it is easy to use in terms of data availability, calculation, and error propagation;  
478 (iii) contrary to energy balance models, it requires limited atmospheric variables; and (iv) it performs  
479 well for Bolivian glaciers (see Fig. S13 in Martin et al., 2018).

### 480 *3.3.2. Present-day temperature and precipitation at the glacial sites*

481 To document paleoclimatic variations, we consider the present as a reference state. We used  
482 homogenized monthly weather station data (Vuille et al., 2008; Martin et al., 2018) to establish the  
483 reference climatic conditions at the four studied paleoglacial sites (Table 1). This record includes 57  
484 temperature stations and 102 precipitation stations spanning 14–23 $^{\circ}\text{S}$  (including the cordilleras and the  
485 Altiplano) over the observational periods 1948–2001 (precipitation) and 1948–2007 (temperature). The  
486 derived mean temperature and annual precipitation values for the four paleoglacial sites studied herein  
487 are reported in Table 1.

Sites	Zongo	Sajama	Tunupa	Luxar
Latitude (°S)	16.2	18.1	19.8	21.0
Longitude (°W)	68.1	68.9	67.6	68.0
Summit elevation (masl)	6088	6542	5321	5440
Mean annual Rainfall (mm)	529 ± 9	329 ± 7	201 ± 15	136 ± 16
Mean annual temperature normalized to 3800 masl <sup>a</sup> (°C)	8.5 ± 0.2	7.7 ± 0.6	6.3 ± 0.2	7.5 ± 0.7

<sup>a</sup> Normalization calculated for a lapse rate of 6.5°C/km

488  
489

491  
492

*Table 1. Present annual rainfall and mean temperature at the studied sites derived from weather station measurements (Vuille et al., 2008; Martin et al., 2018). Observation from 1948 to 2001 for precipitation and 1948 to 2007 for temperature. Temperatures normalized at 3800 masl for comparison purpose.*

493  
494  
495  
496  
497

Equation (2) implies that a given ELA could correspond to several local precipitation-temperature pairs. Therefore, additional constraints are required to derive unique precipitation and temperature pairs for each ELA. To do so, we couple glacier and lake modeling following Blard et al. (2009), Placzek et al. (2013) and Martin et al. (2018), but we extend their approach to the entire deglaciation, between 18 and 10 ka BP.

498

### 3.3.3. Lake model

499

509  
510

We used the lake model of Condom et al. (2004) as modified by Martin et al. (2018). This model divides the Altiplano Basin into lake and soil pixels. All soil pixels are considered to be a reservoir that can be filled until its overflow threshold (*CapaS*) is reached. When precipitation fills the reservoir above *CapaS*, water flows directly to the lake. The flow path of water from the watershed pixel to the lake is not taken into account. As in Blard et al. (2009), the equation used to calculate evaporation is derived from the generalized equation of Xu and Singh (2000) that relies on a simplified energy balance budget. The model is run at a quarterly time resolution and a 5-km spatial resolution. Because gridded products are necessary for the lake model, the temperature and precipitation inputs are derived from the dataset of New et al. (2002). Elevation is based on the 1-arcsecond SRTM DEM. The *CapaS* value was calibrated from the Titicaca watershed for the present period. The modifications of Martin et al. (2018) to the original model of Condom et al. (2004) account for the potential yearly accumulation of seasonal snow stock on watershed pixels. The distributed model computes the melting of this stock using a

511 positive degree day (PDD) value of  $6 \text{ mm } ^\circ\text{C}^{-1} \text{ d}^{-1}$ . Melted snow first fills the soil reservoir until reaching  
512 *CapaS* and overflowing. Further details are available in the Supplementary Information of Martin et al.  
513 (2018).

#### 514 *3.3.4. Coupled lake and glacier modeling*

515 The complete inversion workflow is presented in Fig. 9 and operates as follows. For a given  
516 late-glacial moraine of a paleoglacier, we have access to its age via CRE dating and its ELA via the  
517 AAR method. From this ELA, the relation of Condom et al. (2007) provides a set of local *P-T* solutions  
518 that respect the glacial extent (green path in Fig. 9). From the moraine age, the algorithm considers the  
519 synchronous lake shoreline in the updated dataset of the lake level chronology (see Section 4.1.1). The  
520 paleolake extent corresponding to the selected level is then used to compute the correct hydrologic  
521 balance for different cooling and precipitation values (blue path in Fig. 9). The precipitation field used  
522 in the model includes a local anomaly of enhanced rainfall over the lake region (see Section 3.3.5 and  
523 Supplementary Information). The intersection of these two computed *P-T* curves (sets of solutions) then  
524 defines the precise climatic conditions (i.e. a single *P-T* pair) associated with the glacial extent. We note  
525 that, despite major lake-size variations, both the continuous sediment accumulation in the Coipasa Basin  
526 throughout the study period (Nunnery et al., 2019) and the presence of shoreline records indicate that  
527 the lake did not completely dry prior to the Holocene; this algorithm is therefore applicable to the entire  
528 last deglaciation.

Figure 9. Workflow for paleoclimatic inversions in this study. Lake level evolutions are based on Sylvestre et al. (1999), Placzek et al. (2006), and Blard et al. (2011a), and include the updated Coipasa highstand of the present study (see Section 2.2 and 4.1.1). Glaciological observations are from Soruco et al. (2009) and Rabatel et al. (2013). Moraine ages are either original ages from this study or ages from the literature (see Section 2.3). Present day climatic observations are from New et al. (2002) for gridded products (lake model inputs) and station data (Vuille et al., 2008) for site-specific data (ELA(P,T) inputs). We used the NASA-USGS SRTM 1-arcsecond DEM. Details on the Precipitation Anomaly routine are provided in Section 3.3.5. Input data are italicized.

### 3.3.5. Spatial variability of precipitation induced by precipitation recycling

Martin et al. (2018) recently established the spatial distribution of precipitation during the Tauca Highstand, which evidences the local recycling of lake water superimposed on the global rainfall field. Here, we develop a novel algorithm to account for this lake-induced local precipitation anomaly. In practice, this routine uses the case study of Martin et al. (2018) to mimic the Lake Tauca rainfall anomaly for any given lake geometry and extent. This routine is necessary because they showed this recycling effect to have a non-negligible impact on the spatial distribution of rainfall. Moreover, the four studied glacial sites are contrastingly impacted by this regional precipitation anomaly: whereas Zongo Valley is far from any paleolake influence, the Tunupa and Luxar glaciers, being close to the paleolake centers, were highly impacted by this recycling. To define the geometry of this regional rainfall recycling, we chose an empirical approach that aims to adapt the radial evolution of the Tauca anomaly for any lake configuration of the last deglaciation. In this simplified framework, we define the paleoprecipitation grid as:

$$P(x, y, t) = P_{Present}(x, y) \times \alpha(t) \times \{1 + \beta(lake(t)) \times A(x, y, lake(t))\} \quad (3)$$

where  $P$  is the precipitation field over the basin (two spatial dimensions  $x$  and  $y$ ) at a given time  $t$  of the last deglaciation,  $P_{Present}$  is the present day precipitation field over the basin,  $\alpha$  is a scalar regional amplification factor,  $\beta$  is the amplitude of the recycling anomaly based on the lake surface, and  $A$  is the normalized anomaly grid.  $\beta$  is empirically calibrated using hydrological data from several intertropical lakes (Lakes Mweru, Malawi, Titicaca, and Victoria; see Supplementary Information S4). We obtained a relation fitting  $\beta$  to the lake surface ( $S_{lake}$ , km<sup>2</sup>) with a coefficient of determination ( $R^2$ ) of 0.97.

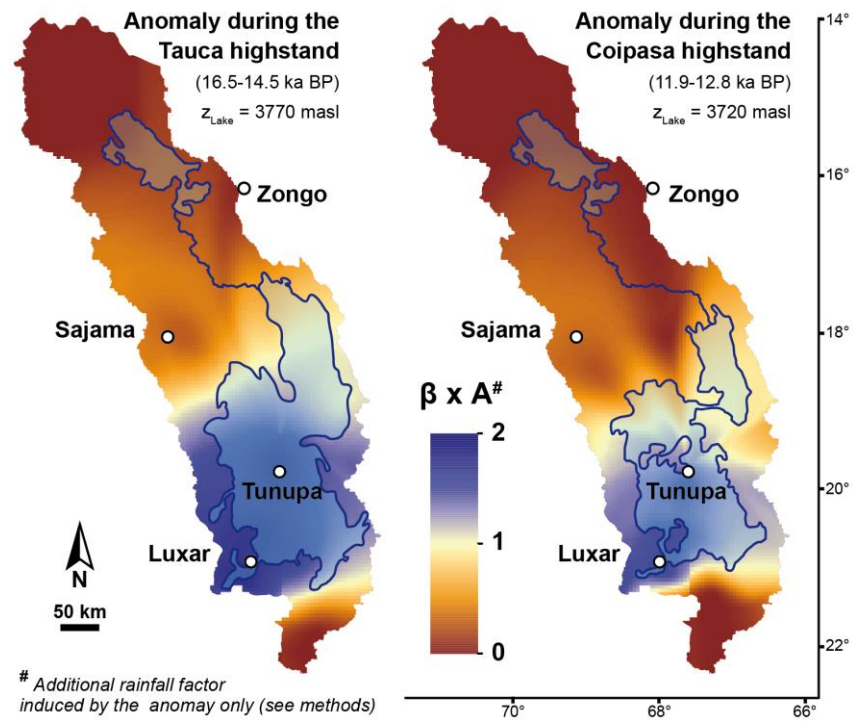

$$\beta = 0.27 \times \ln(S_{lake}) - 2.10 \quad (4)$$

We then used the Tauca highstand case study of Martin et al. (2018) to establish the matrix  $A(x, y, t = \text{Tauca highstand}) = A_{\text{Tauca}}$  and thus isolate the recycling anomaly. To do so, we inverted Equation (3) for  $t = \text{Tauca highstand}$ . The value of  $\alpha_{\text{Tauca}}$  was taken as 2.4, the mean  $P_{\text{Tauca}}/P_{\text{Present}}$  ratio for Zongo Valley and Nevado Sajama, which corresponds to the increased precipitation far from the Tauca paleolake influence. Then,  $\beta_{\text{Tauca}}$  was computed using Equation (4).

564 To adapt the shape of the recycling anomaly to the different lacustrine configurations of the last  
565 deglaciation, we first approached the Tauca anomaly as follows. We first computed the barycenter of  
566 Lake Tauca, which we defined as the point of the lake surface for which the sum of the distances to all  
567 other points on the lake surface is minimal. From this barycenter, we discretized the Altiplano Basin  
568 into 20 regular angular sectors (“pie slices”). The mean radius of the lake for a given sector was  
569 computed considering the mean distance from the barycenter to all Lake Tauca points within that sector.  
570 Then, the radially decreasing anomaly profile (from the barycenter towards the watershed edges) was  
571 averaged per sector and normalized by the mean lake radius of each sector.

572 For the different lake configurations during deglaciation, we then assumed that the recycling  
573 anomaly can be deduced from the Tauca anomaly by some kind of homothety (a transformation  
574 preserving angles and length ratios) centered on the paleo-barycenter of the lake. We therefore implicitly  
575 assume that the redistribution of the local lake-evaporation moisture is primarily driven by the  
576 geographic extent of the water body, and that the wind regime has not drastically changed. For each  
577 paleo-lake extension, we then calculated its barycenter, the angular sectors, and the mean lake radius  
578 per sector, and applied the normalized radial profile (defined by the Lake Tauca extent) to derive  $A(x,$   
579  $y, t)$ .

580 Once  $A(x, y, t)$  was established,  $\beta(t)$  was calculated using Equation (4) and  $\alpha(t)$  was numerically  
581 adjusted so that the climatic input to the lake model is in accordance with the prescribed lake budget  
582 (Fig. 9). The reconstructed anomaly fields (given as  $\beta \times A$ ) for the Lake Coipasa and Lake Tauca  
583 highstands are shown in Figure 10. Further details of the anomaly algorithm are provided in the  
584 Supplementary Information (and graphically illustrated in Fig. S3). The resulting precipitation field is  
585 in excellent agreement with the ELA-derived precipitation map of Martin et al. (2018; see their Fig.  
586 3D).

## 592 4. Results

### 593 4.1. Dating results

#### 594 4.1.1. New shoreline <sup>14</sup>C ages from Incahuasi Island

595 Our new <sup>14</sup>C ages (Table 2) and all previously published radiocarbon ages were calibrated  
596 relative to 2010 using OxCal 4.2 (Ramsey, 2009) and the IntCal13 calibration curve (Reimer, 2013).  
597 This updated dataset was used to refine our knowledge of the evolution of the lake level through time  
598 (Fig. 11). Our four new calibrated ages span the Tauca and Coipasa lake cycles, with sample INC-13-2  
599 (15.97 ± 0.11 cal kyr BP) belonging to the transgressive or deep part of the Lake Tauca cycle. Both  
600 replicates of INC-13-3 (INC-13-3A and INC-13-3B) yield ages of 12.75 ± 0.03 and 12.09 ± 0.13 cal kyr  
601 BP, respectively, precisely coeval with the Lake Coipasa highstand. However, sample INC-13-1 does  
602 not fit the lake level curve established by Blard et al. (2011a); its age of 13.44 ± 0.05 cal kyr BP is 1 kyr  
603 too young to belong to the Tauca highstand and 1 kyr too old for the Coipasa highstand. This single  
604 sample is at odds with the complete dataset, which supports the near-complete evaporation of the lake  
605 between 14 and 13 ka BP (see summary in Blard et al., 2011a). Thus, we consider sample INC-13-1 to  
606 be partially contaminated by modern or dead carbon and exclude it from further discussion.

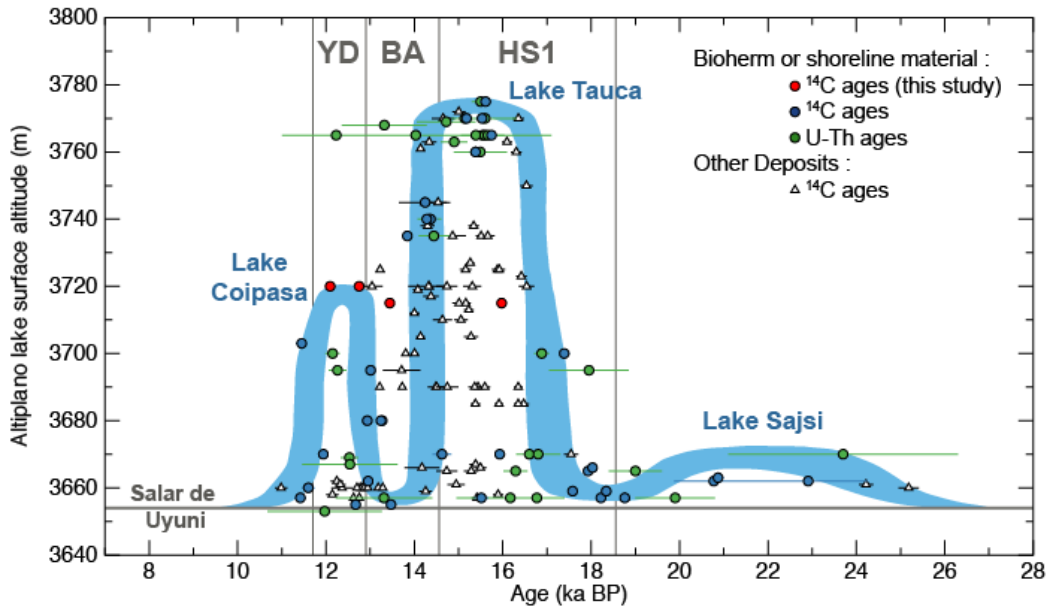

Sample	Material	Latitude Dec°	Longitude Dec°	Elevation masl	Mass mg	δ <sup>13</sup> C ‰ vs PDB	Modern C %	<sup>14</sup> C age <sup>a</sup> yr	Calendar age (1σ) <sup>b</sup> ka BP

607

608 *Table 2. Radiocarbon results for lacustrine bioherms of Incahuasi Island.*

609  
 610 *Figure 11. Paleolake chronology of the southern Altiplano. The blue curve is updated from Blard et al.,*  
 611 *(2011a) to fit a Lake Coipasa highstand 15-20 m above their values, as indicated by our new data (red*  
 612 *points). Other data (blue, green, and white points) are from Blard et al. (2011a), Placzek et al. (2006),*  
 613 *and Sylvestre et al. (1999).*

614  
 615  
 616 The most important update from this new dataset is that the two <sup>14</sup>C ages of bioherms INC-13-  
 617 3A and B belong to the Lake Coipasa (Younger Dryas) event (Fig. 11). These samples stand at 3,720 m  
 618 asl, indicating that the Coipasa highstand was probably 15–20 m higher than previously reported (Blard  
 619 et al., 2011a; Placzek et al., 2006) (Table 2; Fig. 11). This additional lake volume will induce a different  
 620 hydrological balance for Lake Coipasa compared with previous studies.

621 *4.1.2. <sup>10</sup>Be moraine chronology of Zongo Valley*

622 The CRE age results from Zongo Valley are presented in Table 3 and Figure 12. Moraines IP1  
 623 and IP2 (from Smith et al., 2005) exhibit extreme scatter; although it is hard to identify their precise  
 624 timing in the late-glacial period, their position in the valley necessitates that they are older than the other  
 625 moraines. Therefore, they are probably older than IP3 and have an age of at least 17 ka BP. The three  
 626 IP3 ages of Martin et al. (2018) are consistent with the four from Smith et al. (2005). By imposing the  
 627 Bayesian condition that IP4 is a younger object, the age distribution of IP3 is narrowed by a few  
 628 centuries towards older ages, yielding a final age of  $16.9 \pm 0.8$  ka BP. Sample MB4 from moraine IP4  
 629 has an age two times older than those of two other samples from the same moraine that cluster well

630 (36.9 ka BP compared to 16.6 ka BP). This outlier was filtered out by our Bayesian processing when  
631 using IP3 as an older object, giving a final age of  $16.0 \pm 0.8$  ka BP for moraine IP4. The exposure ages  
632 of samples from moraines IP5, CQ1, CQ3, and CQ4 cluster well and form a unique age peak in the PDF.  
633 Our Bayesian processing has only a marginal effect on these ages, which yield respective average values  
634 of  $13.6 \pm 0.8$ ,  $11.6 \pm 0.5$ ,  $10.7 \pm 0.4$ , and  $10.1 \pm 0.4$  ka BP. Due to its upper position and its being  
635 disconnected from the other glacier systems, we could not refine the ages for moraine IP $\alpha$  via Bayesian  
636 filtering and its age PDF is bimodal; the main peak yields an age of  $14.9 \pm 0.9$  ka BP.

637         With CRE ages ranging from 9 to 21 ka BP, moraine MV exhibits substantial scatter. However,  
638 imposing the Bayesian conditions that IP5 and CQ1 are older and younger than MV, respectively,  
639 narrows its age distribution to  $12.6 \pm 0.8$  ka BP. Bayesian filtering also substantially modifies the PDF  
640 of moraine T1, yielding an age of  $12.4 \pm 1.5$  ka BP. Bayesian modifications are more marginal for T2  
641 and T3, yielding respective ages of  $11.0 \pm 0.8$  and  $9.8 \pm 0.9$  ka BP.

643 *Table 3. Zongo Valley <sup>10</sup>Be CRE age results. Recalculated ages from Cerro Telata (Jomelli et al., 2011)*  
644 *are presented in the Supplementary Information (Table S1a) as well as the raw <sup>10</sup>Be and <sup>9</sup>Be*  
645 *measurements of the new samples (Table S1b).*

646

647 *Figure 12. Moraine <sup>10</sup>Be CRE ages in Zongo Valley. The age PDFs of each moraine are color coded to*  
 648 *the map colors. For each PDF, the median age and mean 1σ range are indicated. Boulder ages*  
 649 *contributing to the moraine PDFs beyond 25 ka BP are not represented. Red curves are the raw PDFs*  
 650 *before Bayesian processing, and the shaded histograms are the final PDFs from which ages were*  
 651 *derived (see Section 3.1.5). For moraines IP1 and IP2, the scatter is too important to propose a relevant*  
 652 *central value, and only the central 1σ range is indicated. ‘n’ indicates the number of samples. When n*  
 653 *is reported as ‘n = A – B’, A is the total number of boulders dated on the moraine and B is the number*  
 654 *of boulders considered to be outliers. The blue bars labeled ‘TH’ and ‘CH’ indicate the Tauca and*  
 655 *Coipasa highstands, respectively.*

656 *4.1.3. <sup>3</sup>He moraine chronology of Nevado Sajama*

657 CRE age results for Nevado Sajama are presented in Table 4 and Figure 13. Ages of moraine  
658 M0 show important scatter; imposing the Bayesian condition that M1 is younger does not substantially  
659 narrow the age distribution, which finally yields an age of  $16.1 \pm 1.5$  ka BP. The M1 age PDF comprises  
660 a main peak at c. 15 ka BP, corresponding to four statistically consistent boulder ages, and two minor  
661 peaks corresponding to two older single-boulder ages at 19 and 29 ka BP. We attributed these two older  
662 ages to the production of <sup>3</sup>He in these blocks prior to their deposition atop the moraine (i.e. inheritance)  
663 and thus consider them to be outliers. After Bayesian processing using M0 and M2 as respectively older  
664 and younger objects, the age PDF computed from the four main-peak samples gives an age of  $15.3 \pm$   
665  $0.7$  ka BP. The raw age distribution of M2 presents important scatter; imposing the Bayesian conditions  
666 that M1 and M3 are respectively older and younger narrows its age range to  $15.1 \pm 0.8$  ka BP.

667 The four boulders of M3 yielded clustered ages, with the Bayesian processing only marginally  
668 refining the PDF to yield an age of  $14.9 \pm 0.8$  ka BP. The M4 age is based on a single boulder (SAJ-8)  
669 whose age of  $11.8 \pm 0.7$  ka BP is coherent with the ages of the younger SAJ-7 roche moutonnée ( $10.8$   
670  $\pm 0.5$  ka BP) and the older M3 moraine. The ages of the SAJPH-8 roches moutonnées ( $15.1 \pm 0.7$  ka  
671 BP) is in good agreement with the moraine ages, whereas SAJPH-7 yields an age that is several thousand  
672 years younger than the well-established age of M3. Therefore, SAJPH-7 is probably at odds with the  
673 global chronology and must have been affected by shielding, either by remnants of basal till or by  
674 hillslope colluvium.

686 *4.1.4. <sup>3</sup>He moraine chronology of Cerro Tunupa*

687 CRE age results from Cerro Tunupa are presented in Table 5 and Figure 14. The age distribution  
 688 of moraine M1 moraine exhibits a major peak with four boulder ages clustered around 16 ka BP and  
 689 one outlier older than 20 ka BP that was excluded from the age calculation. After Bayesian processing  
 690 considering M2 as younger than M1, the four remaining boulders yielded an age of 16.3 ± 0.7 ka BP,  
 691 synchronous with the end of the Tauca transgression and the first part of the Lake Tauca highstand. For  
 692 moraine M2, imposing the Bayesian condition that mid-valley roches moutonnées TU-2 and TU-4 are  
 693 younger than M2 excludes one young outlier at 10.7 ka BP and shifts the remaining distribution towards  
 694 older ages, yielding a final age of 15.5 ± 0.5 ka BP.

695           The M3 moraine group exhibits more important scatter. Imposing the Bayesian condition that  
696 the mid-valley roches moutonnées TU-2 and TU-4 are older partly narrows the M3 age distribution,  
697 yielding an age of  $13.4 \pm 1.1$  ka BP. Three roches moutonnées (TU-2, TU-4, TU-13-203) yield ages  
698 clustered around 15.2–15.5 ka BP, and one (TU-13-04) a much older age of  $21.9 \pm 1.3$  ka BP; this  
699 probably indicates an inherited  $^3\text{He}$  component. Given that moraine M3 is deposited above roches  
700 moutonnées TU-2 and TU-13-203, it must have formed during a glacial re-advance (13–12.5 ka BP)  
701 that occurred after the deglaciation at 15.2 ka BP.

 714 *Tauca and Coipasa highstands, respectively.*

715

#### 4.1.5. <sup>3</sup>He moraine chronology of Cerro Luxar

716

CRE age results from Cerro Luxar are presented in Table 6 and Figure 15. The age results at

717

this site present an important scatter, and moraine ages were refined after making several assumptions.

718

For moraine M1, four clustered boulder ages form a major peak around 16 ka BP and the other six

719

boulders returned distinct ages between 21 and 150 ka BP (data are only reported to 30 ka BP in Fig.

720

15). Five of these six older boulders lie atop frontal moraine branches (Fig. 15); subtle inflections of the

721

moraine crest and changes in boulder density suggest that this distal part may be distinct from M1 and

722

thus associated with an older moraine. We therefore consider these six boulders as outliers with

723 significant inherited  $^3\text{He}$  components. Imposing the Bayesian condition that M2 is younger than M1, the  
724 four remaining samples yield an age of  $16.6 \pm 0.7$  ka BP for M1.

725 M2 presents an obvious outlier at 26 ka BP and a bi-modal peak distribution with the major  
726 peak at 17.5 ka BP ( $n = 3$ ) and the minor peak at 15.5 ka BP ( $n = 2$ ). Imposing the Bayesian condition  
727 that M1 is older and the roches moutonnées LUX-6 and LUX-7 are younger than M2 narrows the age  
728 distribution and yields an age of  $15.7 \pm 0.8$  ka BP. The two upper roches moutonnées LUX-6 and LUX-  
729 7 have well-clustered  $^3\text{He}$  ages, indicating a deglaciation of Cerro Luxar around 14.9 ka BP, coeval with  
730 the end of the Lake Tauca highstand. The two boulder ages of M3 lie around 20 ka BP and are not  
731 consistent with the younger ages (15 ka BP) of the stratigraphically older moraines M1 and M2. We  
732 therefore discarded these two boulder ages and derived a Bayesian age distribution for M3 from the  
733 PDFs of M2 and the roches moutonnées, considering that M3 is younger than M2 and older than the  
734 roches moutonnées (see Section 3.1.5). This derived PDF yields an age of  $15.3 \pm 0.7$  ka BP.

 740 *moraine (yellow). Boulder ages contributing to the moraine PDFs beyond 30 ka BP are not represented.*  
 741 *Roche moutonnées and their age distributions are reported on the map in orange. The median age is*  
 742 *reported for each PDF. 'n' indicates the number of samples; when n is reported as 'n = A - B', A is the*  
 743 *total number of boulders dated on the moraine and B is the number of boulders considered to be outliers.*  
 744 *The blue curves are the raw PDFs before Bayesian processing, and the shaded histograms are the final*  
 745 *PDFs from which ages were derived (see Section 3.1.5). Because the raw ages of M3 were not consistent*  
 746 *with the youngest ages of the stratigraphically older moraines, the PDF of M3 was derived from those*  
 747 *of M2 and the upper roches moutonnées (see Section 4.1.5). Blue bars labeled 'TH' and 'CH' indicate*  
 748 *the Tauca and Coipasa highstands, respectively.*

749 **4.2. ELA results**

750 The ELAs computed for each moraine are summarized in Table 7 and Figure 16. This figure  
 751 also provides global context by comparing the ELA results with several other paleoclimatic proxies. All  
 752 ELAs between the LGM and the Holocene range between 4,400 and 4,900 m asl. The paleo-ELA  
 753 changes over the observed periods for Zongo Valley, Cerro Tunupa, and Nevado Sajama are  
 754 approximately 400, 250, and 200 m, respectively. Comparison between the four sites is, however,  
 755 limited because the Tunupa and Luxar glacial records stop at around 13 ka BP, whereas the Zongo and  
 756 Sajama glacial chronologies extend to the Early Holocene (11–10 ka BP). The well-represented

757 moraines emplaced during the 16–15 ka BP period are synchronous with the Lake Tauca highstand  
 758 during Heinrich Stadial 1 (Sylvestre et al., 1999; Blard et al., 2009, 2011a; Placzek et al., 2013; Martin  
 759 et al., 2018). As previously reported by Martin et al. (2018), the ELAs coeval with HS1 show significant  
 760 regional variability, from 4,388 to 4,800 m asl, reflecting significant heterogeneities of the  
 761 paleoprecipitation field.

762 ELAs coeval with the Lake Coipasa highstand (Younger Dryas, c. 12 ka BP) determined from  
 763 the moraines of Nevado Sajama, Zongo Valley, and Cerro Tunupa are characterized by a smaller  
 764 variability, ranging between 4,650 and 4,850 m asl.

 766 *Table 7. ELA, temperature and local precipitation results associated with the CRE moraine ages at the*  
 767 *four studied sites. For Zongo Valley, we did not compute ELA and cooling vs. present for IP1 and IP2*  
 768 *because we were unable to derive a CRE age for these moraines (see Section 4.1.2), nor those for IPa,*  
 769 *which was not part of the main Zongo Valley paleoglacial system (see Section 2.3.1).*  
 770 .

771 **4.3. Paleoclimatic results**

772 The paleoclimatic inversion method described in Section 3.3 enables the determination of both  
 773 the local temperature and precipitation associated with each moraine standstill. These results are  
 774 reported in Table 7 and plotted in Figures 16–18.

 785

786

### 4.3.1. Temperature results at the glacial sites

787

The remarkable setting of the Altiplano watershed allows us to interpret the synchronous local

788

glacier and lake records and temporally reconstruct the local temperature for this region (Fig. 17).

789

Reconstructed temperature shifts during the late-glacial period (compared to present day conditions)

790

range from  $-5$  to  $-2.5$  °C. The four sites show behaviors consistent with progressive warming from  $-5$

791

to  $-2.5$  °C during the Lake Tauca transgression and highstand, followed by colder conditions around  $-$

792

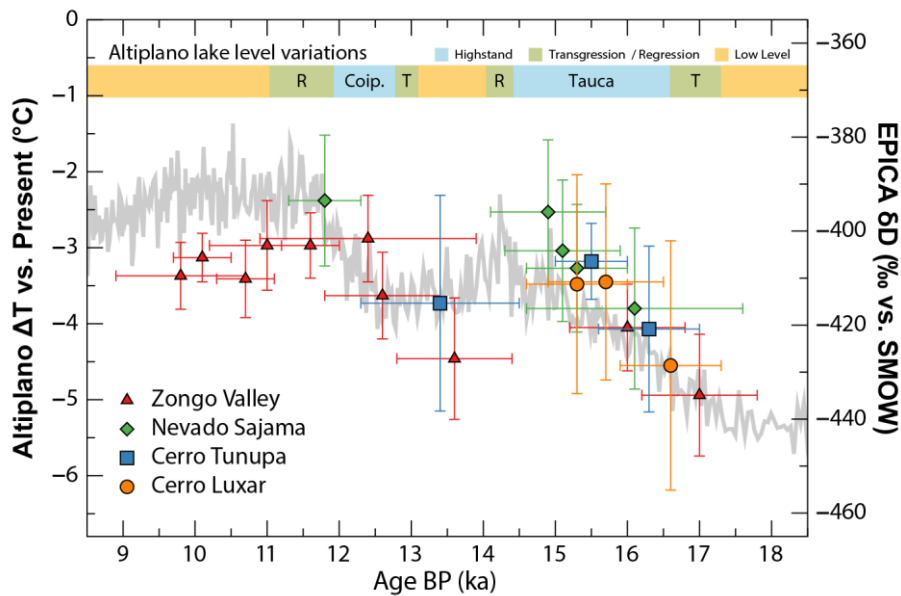

$4$  °C between the two highstands and the progressive stabilization of the temperature shift at around  $-3$

793

°C at the onset of the Holocene. The uncertainties associated with these temperature reconstructions are

794

about  $1$  °C ( $1\sigma$ ).

795

796

Figure 17. Late-glacial local temperature reconstruction inferred from our paleoglacier and paleolake

797

inversion framework (see Section 3.3). Results are expressed relative to the present day mean annual

798

temperature.

799

### 4.3.2. Precipitation results at the glacial sites

800

The reconstructed precipitation changes (reported here as the ratio  $P_{\text{Paleo}}/P_{\text{Present}}$ ) at the four

801

studied sites exhibit significantly different behaviors (Fig. 18). The most remarkable feature is the

802

drastically increased precipitation ratio observed during the Tauca highstand for locations near the center

803

of the paleolake. The rainfall ratio is close to 4 at Cerro Luxar and  $>3$  at Cerro Tunupa,  $\leq 2$  at the Zongo

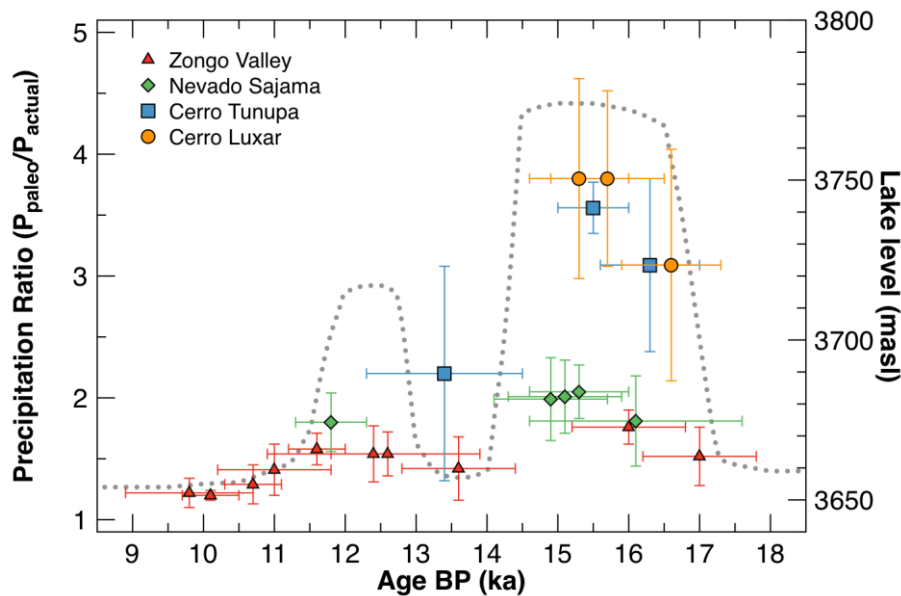

804

and Sajama sites. This trend is due to both (i) the strong north-south gradient in the present-day

805

precipitation over the basin, which amplifies the relative precipitation increase when moisture advection

806 over the basin increases, and (ii) the fact that these sites are too far from the lake to have been affected  
 807 by substantial rainfall amplification due to local water recycling. The higher ratio observed at Cerro  
 808 Luxar compared to Cerro Tunupa might appear counterintuitive because Cerro Luxar is near the  
 809 southwestern shoreline edge of the paleolakes, whereas Cerro Tunupa is in the center of the lake.  
 810 However, this feature directly results from the shape of the regional rainfall field.

811  
 812 *Figure 18. Late-glacial local precipitation reconstruction (derived from the paleoglacier and paleolake*  
 813 *inversion framework; see Section 3.3). Results are normalized relative to present-day precipitation*  
 814 *(Table 1).*

#### 815 4.3.3. Regional temperature and precipitation

816 From the local temperature reconstruction presented in Figure 17, we calculated the mean  
 817 regional temperature (relative to present-day temperature) and precipitation curves over the entire  
 818 deglaciation (17–10 ka BP, both curves in Fig. 16). We derived the regional temperature curve by  
 819 temporally averaging the individual moraine points from the four sites and accounting for their  
 820 individual uncertainties. Using this mean regional temperature curve and its uncertainty envelope, we  
 821 used the inversion algorithm (see Section 3.3) to reconstruct the precipitation field over the basin and  
 822 derive the mean regional annual precipitation curve (Fig. 16). During the deglaciation, the regional  
 823 temperature curve is characterized by a millennial variability. The mean  $\Delta T$  value (relative to present-  
 824 day) increases from  $-5$  to  $-2.5$  °C between 17 and 14.5 ka BP, then decreases to  $-4.5$  °C during the  
 825 ACR, increases up to  $-2.5$  °C during the Younger Dryas, and finally stabilizes around  $-3$  °C at the onset

826 of the Holocene, between 11.5 and 10 ka BP. The uncertainty associated with this signal remains around  
827  $\pm 0.5$  °C during most of the deglaciation period. Precipitation follows similarly: the mean annual rainfall  
828 increases from 530 to 960 mm during the Tauca transgression and highstand, then decreases to 510 mm  
829 between the two highstands, reaches 690 mm during the Coipasa highstand, and finally stabilizes around  
830 450 mm at the onset of the Holocene. The uncertainty associated with this signal never exceeds  $\pm 25$   
831 mm during the study period.

## 832 **5. Discussion**

### 833 **5.1. Glacial chronologies**

#### 834 *5.1.1. Zongo Valley*

835 The updated glacial chronology of Zongo Valley yields meaningful results. Only three of the 13  
836 analyzed moraines show very high scatter: IP1, IP2, and MV. Given their location, IP1 and IP2 must be  
837 older than 17 ka BP, and they are not discussed further in this study. The Bayesian constraints brought  
838 by IP5 and CQ1 on MV enabled us to derive its age with an uncertainty better than 1 kyr. Other moraines  
839 either present clear outliers (e.g. IP4) or relatively clustered ages. For these moraines, the Bayesian  
840 filtering had only a marginal effect on the age distributions. The exceptions to these general observations  
841 are the T1 and T2 Telata moraines that exhibit significant scatter; their age distributions were  
842 importantly modified by the Bayesian constraints. Nonetheless, their ELAs are in good agreement with  
843 those of the same age throughout the rest of the valley. IP3 and IP4 indicate that the local last glacial  
844 maximum (LLGM) occurred before 17 ka BP. The ELA changes remain limited between 17 and 13.5  
845 ka BP in Zongo Valley ( $\Delta\text{ELA} < 100$  m). A 10-km horizontal retreat from IP5 to CQ4 subsequently  
846 occurred over a 3–3.5 kyr interval, corresponding to an ELA rise of almost 300 m. IP5 is coeval with  
847 the ACR (14.5–12.9 ka BP) and CQ1 with the Younger Dryas (12.8–11.5 ka BP). The CQ3, CQ4, and  
848 Telata moraines are concomitant with the Pleistocene-Holocene transition.

849 *5.1.2. Nevado Sajama*

850 Smith et al. (2009) used  $^{36}\text{Cl}$  cosmogenic data to establish the first glacial chronology for  
851 Nevado Sajama. In agreement with their results, our  $^3\text{He}$  dataset confirms the presence of late-glacial  
852 moraines on Nevado Sajama. However, the important scatter of their  $^{36}\text{Cl}$  ages (possibly due to inter-  
853 sample variability in Cl content; Schimmelpfennig et al., 2009) precludes a more detailed comparison  
854 with our results.

855 Nevado Sajama records a major glacial advance around 16 ka BP, coeval with the end of the  
856 transgression and the beginning of the Lake Tauca highstand. The ELA shift between 16 and 15 ka BP  
857 is less than 60 m (2 km of horizontal retreat), suggesting that climatic conditions remained relatively  
858 stable during this period. The age of moraine M4 is coeval with the end of the Coipasa highstand, and  
859 its corresponding ELA (4,871 m asl) is not significantly higher than that at the end of the Tauca  
860 highstand as observed on moraine M3 (ELA = 4,800 m asl). However, our results do not permit  
861 evaluation of whether the Sajama glaciers receded above the M4 moraine front or remained stationary  
862 between 15 and 12 ka BP. A major glacial retreat probably occurred after the end of the Coipasa  
863 highstand-Younger Dryas stadial.

864 *5.1.3. Cerro Tunupa*

865 Our recalculation does not substantially change the initial conclusions of Blard et al. (2009,  
866 2013a). As they reported, the Tunupa moraines record a major glacial advance around 16.3 ka BP (M1),  
867 followed by the standstill that built moraine M2 synchronous to the Lake Tauca highstand-Heinrich 1  
868 stadial ( $15.5 \pm 0.5$  ka BP). Our  $^3\text{He}$  CRE ages of the upstream roches moutonnées confirm that this  
869 standstill was followed by a rather abrupt glacial retreat after 15 ka BP and an associated ELA shift of  
870 200 m just before (or synchronous to, within uncertainties) the Lake Tauca regression at 14.5 ka BP  
871 (Fig. 14).

872 *5.1.4. Cerro Luxar*

873 As recently established by Martin et al. (2018), moraines M1 and M2 indicate rather stable  
874 climatic conditions synchronous to the Lake Tauca highstand from 16.1 to 15.2 ka BP, with an ELA

875 standing between 4,700 and 4,750 m asl. Additionally, our  $^3\text{He}$  CRE ages of upstream roches  
876 moutonnées indicate a rapid glacial retreat just after 15 ka BP and nearly synchronous to the Lake Tauca  
877 regression (Fig. 15), as observed at Cerro Tunupa.

### 878 *5.1.5. Overview*

879 The Sajama, Tunupa, and Luxar moraines present rather similar glacial chronologies. They all  
880 record a major glacial standstills or re-advances around 16–15 ka BP coeval with the Tauca highstand.  
881 All three sites experienced a significant glacial retreat during the last centuries of the highstand or during  
882 the Lake Tauca regression. Tunupa and Luxar experienced the most significant ELA decrease, likely  
883 due to their proximity to the center of the paleolake. On Nevado Sajama, the ice tongue stabilized in the  
884 upper part of the valley during the Younger Dryas before later retreating.

885 Zongo Valley exhibits a slightly more complex pattern: although the Tauca moraine is also  
886 observed in this valley, the paleoglaciation there is characterized by a LLGM older than 17 ka BP, and  
887 the persistence of climatic conditions similar to those during the LLGM until 13.5 ka BP. The  
888 subsequent rapid and massive glacial retreat was followed by a marked standstill during the Younger  
889 Dryas and a progressive retreat during the Early Holocene. This geographic contrast between the  
890 paleoglacial behaviors of the Cordillera Real and the southeast Altiplano is consistent with the present  
891 day climatic setting of Andean glaciers (Sagredo and Lowell, 2012), probably due to the proximity of  
892 the Amazonian moisture source to Zongo Valley.

## 893 **5.2. Robustness of the paleoclimatic inversion**

### 894 *5.2.1. Uncertainties on reconstructed temperatures*

895 Our temperature reconstruction for the deglaciation period (Fig. 17) has an average uncertainty  
896 of  $\pm 0.5$  °C, which was propagated from all uncertainties arising from the parametrizations of the lake  
897 and glacier models. Some model parameters, such as AAR, are theoretically similar throughout a given  
898 valley, implying that the reported errors should be considered maximum values. Importantly, the  
899 temperature reconstructions for different sites yield similar and consistent values: the linear temperature  
900 increase between 17 and 15 ka BP (during the deglaciation) is defined by the paleoglacial records of

901 each of the four glaciated valleys. Nearly synchronous temperatures are compatible within less than 0.5  
902 °C, highlighting the regional consistency of our reconstruction. The cooling period during 14–13 ka BP  
903 is evidenced by two moraines from different glacial sites (Zongo and Tunupa) that yield consistent  
904 temperature values. The final warming period during 13–11 ka BP is defined by several moraines of  
905 Zongo Valley and one moraine on Nevado Sajama, all of which are compatible within uncertainties. In  
906 summary, the trend in the temperature record is significant.

907 *5.2.2. The climatic conditions recorded by a moraine exposure age:*  
908 *significance, uncertainty and signal filtering*

909 Traditionally, exposure ages of block sitting on top moraines are considered as documenting the  
910 final episode of sediment piling and of moraine building, i.e. the final stage of a glacier advance or still  
911 stand (Bennett, 2001). Even if uncertainties remain on the exact timing of block stabilization regarding  
912 the glacier retreat after a glacier advance (Eichel et al., 2018), as well as on the CRN inheritance of a  
913 block acquired during its final supraglacial period of transport (Briner et al., 2005; Heyman et al., 2011),  
914 recent dating of Little Ice Age moraines in the Alps have shown that <sup>10</sup>Be exposure ages of blocks sitting  
915 on moraines are nearly synchronous with the glacier advances documented by historical chronicles (e.g.  
916 Schimmelpfennig et al., 2014). Such examples in the Alps suggests that this uncertainty might be lower  
917 than 0.1 kyr, i.e. much lower than the uncertainties reported for the exposure ages in the present study  
918 (0.5 to 1 kyr). The exact representativeness of CRN ages of boulders on moraine therefore probably has  
919 little bearing on the interpretation of the moraine ages described in this study. Nevertheless, it should be  
920 noted that the final uncertainty on the moraine ages, as well as the propagation of this uncertainty on the  
921 paleolake level to calculate paleo-temperatures and paleoprecipitation, implies that the paleoclimatic  
922 curves obtained are smoothed at the millennial scale and filtered from their high-frequency content. As  
923 such, our paleoclimatic reconstructions based on moraines preclude discussion on high frequency  
924 climate variation and abrupt transition at the centennial scale.

925           5.2.3. *Comparison with previous regional temperature and precipitation*  
926 *reconstructions*

927           Our reconstruction provides the first continuous records of absolute temperature and  
928 precipitation throughout the deglaciation period for the Altiplano. As such, our reconstructions can only  
929 punctually be compared to other regional studies. Blard et al. (2009) and Martin et al. (2018) focused  
930 on the Lake Tauca highstand (16–15 ka BP), whereas Placzek et al. (2013) established mean  
931 precipitation and temperature records for three successive lake highstands: Lake Sajsi (24–20 ka BP),  
932 Lake Tauca (16–15 ka BP), and Lake Coipasa (12 ka BP). Our temperature and precipitation records  
933 for the Lake Tauca highstand are consistent with the 3 °C cooling and mean regional precipitation of  
934 900 mm yr<sup>-1</sup> ( $P_{\text{Tauca}}/P_{\text{Present}} = 2.2$ ) obtained by Martin et al. (2018; square symbols in Fig. 16). However,  
935 these paleoclimatic conditions differ from the cooler ( $\Delta T_{\text{Tauca}} \approx -4$  to  $-7$  °C) and drier conditions  
936 ( $P_{\text{Tauca}}/P_{\text{Present}} < 2$ ) inferred by Blard et al. (2009) and Placzek et al. (2013) for the Lake Tauca highstand.  
937 This discrepancy probably arises from the combination of three factors. First, our study uses an up-to-  
938 date and more accurate approach to estimate the spatial distribution of precipitation. This new approach  
939 is based on our recent work (Martin et al., 2018), and is more relevant than those of the pioneer studies  
940 of Blard et al. (2009) and Placzek et al. (2013) because the spatial distribution of precipitation now  
941 accounts for both the entire regional ELA variability and the distributed lake recycling anomaly  
942 throughout the southern part of the catchment. Second, we used a different model to convert paleo-ELAs  
943 into paleoclimatic variables ( $P$ ,  $T$ ). Blard et al. (2009) applied a PDD model, which tends to overestimate  
944 the temperature sensitivity of ablation in arid regions receiving snow accumulations  $< 500$  mm yr<sup>-1</sup>  
945 (Blard et al., 2011b; Sicart et al., 2008), whereas we used the robust empirical model of Condom et al.  
946 (2007). Third, we used newer data to define the present-day climatic conditions: whereas Placzek et al.  
947 (2013) considered a mean annual temperature of 10.8 °C at 3,800 m asl for the entire Altiplano, our  
948 compilation of present-day weather station data yielded spatially variable means from ~6.3 to 8.5 °C at  
949 3,800 m asl (Table 1; Martin et al., 2018). Regarding the Early Holocene period (10–8 ka BP), Jomelli  
950 et al. (2011) reported a cooling of ~3 °C based on Cerro Telata moraines, which is similar to that derived  
951 herein for the nearby Zongo Valley. Although they used a PDD model, the consistency with our results

952 is likely due to the fact that this region is fed by abundant precipitation (annual snow accumulation >  
953 1,000 mm a<sup>-1</sup>). Indeed, under such wet conditions, PDD models yield an ELA-climate sensitivity similar  
954 to that of the empirical model used here (Condom et al., 2007).

955 The glacier ice core  $\delta^{18}\text{O}$  records from Huascarán (Peru) and Sajama (Bolivia) have been used  
956 to suggest that Andean temperatures during the deglaciation were similar to those in Greenland and the  
957 North Atlantic, with HS-1 notably being the coldest period of the past ~19 ka BP (Thompson et al.,  
958 1995, 1998). However, other studies have argued that the O isotopic compositions of tropical ice cores  
959 do not provide a pure temperature signal because they are also controlled by the composition of  
960 precipitation and atmospheric processes (Ramirez et al., 2003). The  $\delta^{18}\text{O}$  signal in tropical ice may also  
961 have been biased by vapor originating from Lakes Tauca and Coipasa, water sources with high  $\delta^{18}\text{O}$   
962 values (Quesada et al., 2015).

### 963 **5.3. Regional and global paleoclimatic implications**

964 Our reconstruction of both absolute precipitation and temperature during the last deglaciation  
965 represents a unique dataset documenting the regional and global paleoclimatic mechanisms affecting  
966 the southern Tropical Andes. Our new reconstructions reveal that (i) precipitation variability over the  
967 Altiplano reacted synchronously with the Greenland-Atlantic dynamic during the deglaciation  
968 (Andersen et al., 2004; McManus et al., 2004), whereas (ii) temperatures were in phase with Antarctic  
969 temperature fluctuations (Jouzel et al., 2007). These new observations are key in deciphering the  
970 paleoclimatic connections between the Northern and Southern Hemispheres and the Tropics.

#### 971 *5.3.1 Precipitation results*

972 Several studies have identified connections between precipitation in the Tropical Andes and the  
973 abrupt climatic oscillations of the Northern Hemisphere during the last deglaciation (Baker et al., 2001;  
974 Blard et al., 2011a; Crivellari et al., 2018; Fritz et al., 2007; Gayo et al., 2012; Haug, 2001; Licciardi et  
975 al., 2009; Martin et al., 2018; Placzek et al., 2006). However, until now, a continuous absolute record  
976 of Altiplano paleoprecipitation during the last deglaciation was not available. Filling this gap, our

977 reconstruction supports an interhemispheric connection between precipitation over the Altiplano,  
978 temperatures in Greenland, and the Atlantic meridional overturning circulation (AMOC) during the  
979 entire deglaciation (Fig. 16). However, our results do not allow us to extend this observation beyond the  
980 Altiplano Basin to the entire tropical Andes.

981 Martin et al. (2018) reconstructed the spatial variability of precipitation at unprecedented resolution  
982 during the Lake Tauca highstand (Heinrich 1 event) and suggested that atmospheric mechanisms  
983 modulated the SASM, producing major precipitation changes over the Altiplano. Increases in  
984 precipitation likely resulted from southward displacement and intensification of the Bolivian High (a  
985 high-pressure cell), which enabled substantial westward moisture advection towards the Altiplano  
986 Basin. A continental forcing of this phenomenon might be fluctuations of the South Atlantic  
987 Convergence Zone (SACZ), which controls the position and intensity of the Bolivian High (Lenters and  
988 Cook, 1999) and showed extreme fluctuations during the Tauca highstand (“Mega-SACZ” events;  
989 Strikis et al., 2015). Similar events can be invoked to explain the abundant precipitation during the  
990 Coipasa highstand.

991 The mechanisms linking changes of the SASM to the global climate remain debated. Additional  
992 reconstructions of continental precipitation during the last deglaciation based on inverse glacier  
993 modeling could contribute to better identifying the controlling atmospheric patterns. However, the  
994 southward migration of synoptic atmospheric features during cold periods in the North Atlantic has been  
995 repeatedly observed or modeled for the Northern Westerlies (Roe and Lindzen, 2001; Zhang et al.,  
996 2014), the Intertropical Convergence Zone (Crivellari et al., 2018; Kanner et al., 2012; Peterson, 2000),  
997 and the Southern Westerlies (Anderson et al., 2009; Denton et al., 2010; Toggweiler et al., 2006).

### 998 *5.3.2 Temperature results*

999 Only a few empirical studies have suggested common Antarctic and Tropical atmospheric  
1000 temperature patterns. The meta-analysis of Tropical Andean moraine ages by Jomelli et al. (2014)  
1001 showed that most Tropical Andean glaciers had a greater extent during the ACR than during the Younger  
1002 Dryas. They also used a transient general circulation model (GCM) simulation to show that the  
1003 connection between Southern Hemispheric and Tropical temperatures results from a combination of

1004 several atmospheric mechanisms, including AMOC modulation, CO<sub>2</sub> level, precipitation, vegetation,  
1005 and local heat budgets. However, Groot et al. (2011) presented a contradictory paleotemperature dataset;  
1006 based on a continuous 284-kyr-long pollinic record from a core drilled in Lake Fúquene, Columbia  
1007 (5°N, 2,540 m asl), they asserted that temperature fluctuations in Columbia follow North Atlantic-  
1008 Greenland fluctuations on glacial-interglacial time scales.

1009         In this context, our results show that an Antarctic-like temperature pattern characterized the high  
1010 Andes, at least as far north as 15°S, during the last deglaciation, with a linear warming trend of ~2.5 °C  
1011 during 17–14.5 ka BP, a return to conditions ~1.5 °C colder during the ACR (14.5–13 ka BP), a second  
1012 warming of ~1.5 to 2 °C during 13–12 ka BP, and a subsequent stabilization of temperatures during the  
1013 early Holocene (Fig. 17). This trend is remarkably consistent with temperature variations in Antarctica  
1014 over the same period, as recorded by the H isotopic composition of ice cores (Fig. 17). This correlation  
1015 suggests a homogeneous, large-scale temperature evolution in the Southern Hemisphere, i.e. from the  
1016 southernmost latitudes to the southern Tropical Andes, during the last deglaciation. This similarity  
1017 between tropical and Antarctic temperatures may also result from a common response of both regions  
1018 to independent, but synchronous, forcings. Barker et al. (2011) established that temperature variations  
1019 in the Antarctic and Southern Ocean regions are partially controlled by the bipolar seesaw, and thus, by  
1020 AMOC fluctuations. Moreover, at seasonal to inter-annual time scales, the southerly flow of Antarctic  
1021 glacial air masses is thought to control significant cooling in the southern and mid-latitude Andes  
1022 (Schneider et al., 2003). If the frequency of such airflow intrusions increased and persisted over  
1023 millennial timescales, it could explain the Antarctic-like temperature pattern of the Altiplano as  
1024 observed herein.

1025         However, the temperature pattern of the Altiplano observed during the last deglaciation could  
1026 also reflect a regional response to variations in regional precipitation via their impact on the energy  
1027 budget. This could explain the positive correlation between precipitation and temperature over the  
1028 Altiplano, with the warmest periods being associated with the wettest events (Fig. 16). Further studies  
1029 employing high-resolution GCM simulations over that Late Pleistocene-Holocene transition will be key  
1030 to disentangling these various scenarios.

#### 1031 **5.4. A note on the use of glacial fluctuations as paleoclimatic proxies**

1032 An important methodological conclusion that can be drawn from our paleoclimatic  
1033 reconstruction is that paleoglacial fluctuations may not simply be a proxy for temperature that can be  
1034 directly used to infer large-scale paleoclimatic changes. In dry regions where glacial mass balances are  
1035 under a precipitation-limited regime, such a simplification may yield inaccurate conclusions. For  
1036 example, our data show that, despite atmospheric warming during the last deglaciation (17–15 ka BP),  
1037 Altiplano glaciers advanced due to increased precipitation concomitant with the Lake Tauca highstand  
1038 (Fig. 18). Although temperature is the main control of glacier dynamics, substantial precipitation  
1039 variations modulate glacial advances and retreats, and can counterbalance or even surpass the effects of  
1040 slight warming. For example, according to equation (2), a precipitation increase of 1000 to 1600 mm.yr<sup>-1</sup>  
1041 can compensate a 2°C warming. Such glacier fluctuations regionally driven by precipitations might  
1042 appear as a rather counter intuitive result. According to this mechanism, local moisture increase during  
1043 the YD may have triggered glacier readvances that have erased the moraines left by the former and  
1044 colder period of the ACR.

1045 Such obliteration could be of limited spatial extent, and could have occurred in areas affected by a  
1046 marked local increase in precipitation, such as promoted by moisture recycling in the vicinity of a large  
1047 lake. This might explain why preserved ACR moraines are less prevalent in the central Altiplano than  
1048 in other regions of the wet Tropical Andes (Jomelli et al., 2014). Therefore, the potential importance of  
1049 the respective roles of precipitation and temperature should be carefully considered in future  
1050 paleoclimatic studies relying on paleo-ELA reconstructions, ideally by coupling the interpretation of  
1051 paleo-ELA inventories with independent proxies of precipitation and temperature.

## 1052 **6. Concluding remarks**

1053           In Zongo Valley, the oldest glacial extent for which geochronological constraints are available  
1054 ( $\geq 17$  ka BP) was approximately maintained until 13.5 ka BP, and was followed by a massive glacial  
1055 retreat until the early Holocene. This retreat was associated with an ELA variation of 300 m. Nevado  
1056 Sajama, Cerro Tunupa, and Cerro Luxar exhibit moraines synchronous with the Tauca Lake highstand  
1057 (c. 16 ka BP), followed by different retreat timings. For these three sites, the ELA rose by  $\sim 200$  m after  
1058 the end of the Tauca highstand.

1059           At the scale of individual glacial sites, our precipitation reconstruction is characterized by a  
1060 strong spatial variability during the Tauca highstand due to lake-enhanced precipitation. At the regional  
1061 scale, precipitation variations over the Altiplano basin were paced by the Northern Hemispheric  
1062 dynamic, with the wettest period on the Altiplano being synchronous to the cold HS1a and Younger  
1063 Dryas events. Our regional temperature reconstruction shows good consistency with Antarctic  
1064 temperatures: the temperature curve (relative to present-day temperatures) defines (i) a linear warming  
1065 trend from  $-5$  to  $-2.5$  °C during 17–14.5 ka BP, (ii) a return to colder conditions ( $-4$  °C) during 14.5–  
1066 13 ka BP, (iii) a second warming after 13 ka BP (to  $-3$  °C), followed by (iv) the stabilization of  
1067 temperatures into the Early Holocene.

1068           Because the conditions within the Altiplano basin were sufficiently cold for glacial settlement  
1069 and growth, glacial dynamics were driven by the regional precipitation increase during the Lake Tauca  
1070 and Lake Coipasa highstands, which explains the abundance of morainic records synchronous with the  
1071 Tauca highstand despite warming temperatures. Outside of these periods, glaciers were driven by large-  
1072 scale temperature variations. Our results provide an original framework for understanding why the ACR  
1073 is more represented than the Younger Dryas among morainic records throughout the Tropical Andes,  
1074 and why North Atlantic cooling events (coeval with Altiplano lake highstands), that enhanced local  
1075 precipitation, correspond to glacial advances over the Altiplano basin. These results exemplify that  
1076 paleoglacial variations cannot solely be interpreted in terms of temperature variations, and that regional  
1077 precipitation patterns can significantly affect glacial dynamics.

## 1078 Acknowledgments

1079 This work was funded by the INSU EVE-LEFE program and the ANR Jeunes Chercheurs  
1080 GALAC project (ANR-11-JS56-011-01). We greatly appreciated the logistical support of the Institut de  
1081 Recherche pour le Développement (IRD) of La Paz (Bolivia) during our field trips between 2010 and  
1082 2013. The ASTER French national AMS facility (CEREGE, Aix-en-Provence) is supported by  
1083 INSU/CNRS, the ANR through the “Equipements d’Excellence” program, IRD, and CEA. Field  
1084 measurements of mass balance and ELA on Bolivian and Ecuadorian glaciers were provided by the  
1085 Andean part of the Service National d’Observation GLACIOCLIM, funded by the French IRD, the  
1086 Universidad Mayor de San Andres (IGEMA, IHH) in Bolivia and the Insituto Nacional de Meteorologia  
1087 e Hidrologiain Ecuador.

1088 We warmly thank C. Hautefeuille and Benj Barry for their contributions to the Luxar datings,  
1089 P. Burnard, B. Tibari, and L. Zimmerman for essential help with the SFT mass spectrometer and related  
1090 devices during analytic sessions, V. Mariotti and M. Prémaillon for their help during field trips and  
1091 sample collection, Flo Gallo, M. Protin, and D. Brunstein for their support during  $^{10}\text{Be}$  chemical  
1092 analyses, and L. Tissandier and Y. Marrocchi for help with SEM and mineral analyses. We are grateful  
1093 to the SARM-CNRS for high quality chemical analyses. E. Davy, R. Joussemet and the STEVAL crew  
1094 (GeoRessources, Nancy) are acknowledged for their technical support during sample crushing and  
1095 mineral separation. We thank R. Dennen and rd-editing.com for in-depth language editing. We are  
1096 deeply grateful for the constructive feedback provided by the reviewers, which helped to improve the  
1097 manuscript clarity.

## 1442 S.2. Hydrologic connection between the Altiplano sub-basins

1443 We used the shoreline archive to provide hydrological constraints on our climatic inversions  
1444 based the on hydrologic budget of the southern basin lake at a given level. Because the hydrologic  
1445 connection between the four basins of the Altiplano during the late-glacial period has not been proven,  
1446 computing the relevant hydrologic budget required that we determine which basins were connected to  
1447 the southern basin for a given set of  $\Delta T$  and  $\Delta P$  values (relative to present-day values).

1448 We computed the hydrological balance of each sub-basin watershed balance sequentially to  
1449 evaluate the connection between each basin and its downstream counterpart(s). First, we computed the  
1450 Titicaca overflow toward the Poopo basin, then the annual hydrologic budgets for the Poopo basin,  
1451 allowing lake-level adjustments from one year to another until reaching a steady state. If this steady  
1452 state corresponds to an overflow towards the Coipasa basin, we determine the corresponding input for  
1453 the Coipasa. We applied the same approach to the Coipasa basin to see if it overflows into the Uyuni  
1454 basin. We thusly identified the basins hydrologically connected with the southern basin, for which we  
1455 know the lake level from shoreline ages. We finally computed the hydrological budget for the identified  
1456 basins and solved for  $\Delta T$  and  $\Delta P$ .

1457 **S.3. Calculation of the lake-induced precipitation anomaly, computation of the  $A$  grids**

1458           The initial steps of this calculation are presented in Section 3.3.5. Within each sector, the  
1459 punctual  $A_{\text{Tauca}}(x, y)$  value was associated to its normalized distance  $r^*_s$  to the barycenter, taken as the  
1460 actual distance divided by the sector's lake radius. From these values, a scatter plot of  $A_{\text{Tauca}} = f(r^*_s)$  was  
1461 constructed for each sector, and a curve averaging the point cloud was constructed. Thus, for the Tauca  
1462 highstand, we produced a set of 20 curves describing the radial evolution of the anomaly from the  
1463 barycenter of Lake Tauca along the normalized distance  $r^*_s$ . Because each of these curves averages this  
1464 behavior over a given angular sector, we associated each  $A(r^*_s)$  curve with  $\theta_s$ , the angle (in radians)  
1465 between the bisector of sector S and a reference vector (due south).

1466           Then, for any time  $t$  of the last deglaciation, we proceeded as follows. We first derived the lake  
1467 level from the shoreline dataset. We then derived the lake extent from this elevation and the DEM of  
1468 the basin, and calculated its barycenter. From the barycenter, we divided the basin into 20 angular sectors  
1469 and calculated the mean lake radius per sector (see Section 3.3.5). We then calculated  $r^*_i$  and  $\theta_i$  for each  
1470 point  $i$  in the sector. We then used the set of 20  $A(r^*_s)$  curves in  $\theta_s$ - $r^*_s$  space to perform a 2D polar  
1471 interpolation of the values of  $A$  in  $\theta_i$ - $r^*_i$  space. We were thus able to calculate the grid  $A$  for any lake  
1472 configuration of the study period. This algorithm was implemented such that during the Tauca  
1473 highstand, the anomaly algorithm was bypassed and the grid  $A$  input into the lake model was the original  
1474 grid directly derived from the results of Martin et al. (2018). The reconstructed anomaly fields (given  
1475 as  $\beta \times A$ ) for the Coipasa and Tauca highstands are shown in Figure 10, and a graphical illustration of  
1476 the anomaly algorithm is provided in Figure S3.

$$\underline{\underline{P}}(t) = \underline{\underline{P}}_{\text{Present}} \cdot \alpha \cdot (1 + \beta \cdot \underline{\underline{A}})$$

$\underline{\underline{A}} = f(\text{Lake Tauca}, \text{Lake}(t))$

For each angular sector :  
 Mean lake **S**horeline distance to **B**arycenter :  $\overline{r_{B-S}}$

**KNOWN :** (Martin et al., 2018)

- $P_{\text{Tauca}} / P_{\text{Present}}$
- $\alpha_{\text{Tauca}}$
- $\beta_{\text{Tauca}}$

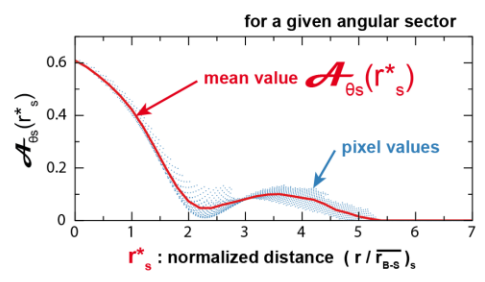

➔  $\underline{\underline{A}}_{\text{Tauca}}$

**WANTED :**

$\underline{\underline{A}}(t)$

For each **angular sector**, considering the angle  $\theta_s$ , to the bissector of each sector, we consider the  $\mathcal{A}_{\theta_s}(r_s^*)$  mean curve as follow :

For each pixel  $i$  in the basin, we consider its radial coordinate relative to the barycenter :  $r_i$  and  $\theta_i$   
 And then normalize  $r_i$  considering its **angular sector** :

$$r_i \rightarrow \left( \frac{r}{r_{B-S}} \right)_i = r_i^*$$

$$\mathcal{A}_{\theta_s}(r_s^*) \text{ in } (\theta_s, r_s^*)$$

$$(\theta_i, r_i^*)$$

2D interpolation of the  $A_i$  values of  $\underline{\underline{A}}(t)$  on the  $(\theta_i, r_i^*)$  grid,  
 based on the  $\mathcal{A}_{\theta_s}(r_s^*)$  curves in the  $(\theta_s, r_s^*)$  grid ➔  $\underline{\underline{A}}(t)$

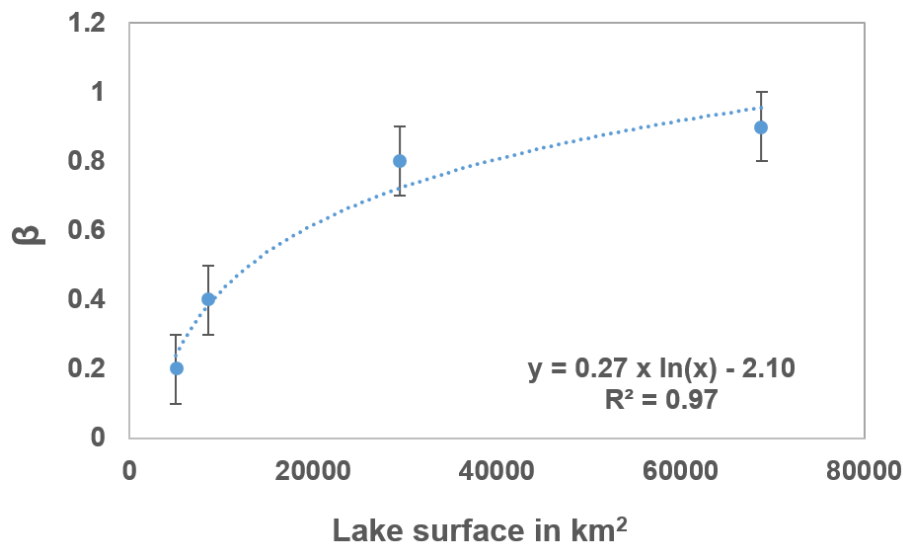

Figure S3. Workflow to compute the precipitation anomaly grid. The workflow describes the computation of matrix  $A$  as described in Section 3.3.5 and Equation (3). Matrix  $A$  was computed based on the Tauca highstand case study of Martin et al. (2018). The matrix  $A$  for the Tauca highstand was discretized from the barycenter of Lake Tauca into different angular sectors (“pie slices”) such that it can be summed as a set of curves describing the decrease of  $A$  with distance from the barycenter. These curves were then used for any lake configuration during the last deglaciation by employing a scaling procedure that accounts for the location of the lake and its spatial extent. We note that for legibility, the schematic diagram  $s$  divided into eight angular sectors instead of the twenty used in the computation.

1486 **S.4. Calculation of the lake-induced precipitation Anomaly, calibration of the  $\beta$  parameter**

1487 Based on empirical precipitation data for present-day lakes, the amplification value  $\beta$  seems to  
 1488 be linked to lake size (Table S4, Fig. S4). Because the sizes of Lake Coipasa (32,300 km<sup>2</sup>) and Lake  
 1489 Tauca (52,000 km<sup>2</sup>) differ, and because we also dealt with their transgressive and regressive states  
 1490 synchronous with the reported ice extents, we calibrated  $\beta$  to account for this size-dependence (see  
 1491 Section 3.3.5 and Equation 4) using the data presented in Table S4 and Figure S4.

Lake	Surface (km <sup>2</sup> )	Observed $\beta$	Uncertainty
Lake Mweru	5022	0.2	0.1
Lake Titicaca	8562	0.4	0.1
Lake Malawi	29429	0.8	0.1
Lake Victoria	68800	0.9	0.1

1496 **S.5. Impact of the scaling scheme model on the CRE age computations**

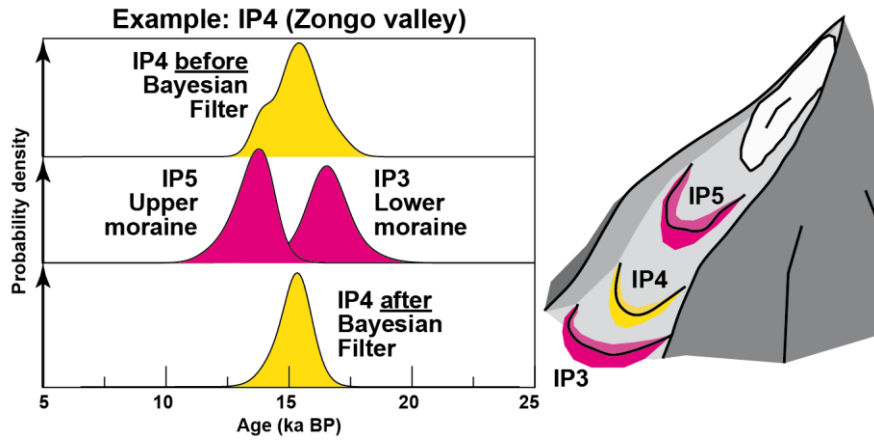

1497 To assess the dependence of the computed ages to the scaling procedure, we used CREp  
1498 (<https://crep.otelo.univ-lorraine.fr>) to re-compute all the ages of this study using a different scaling  
1499 framework. In Fig. S5, we compare the ages obtained with the Lal/Stone ('Lm') time-dependent scaling  
1500 model (Balco et al., 2008) and the geomagnetic database of Muscheler et al. (2005) to those obtained  
1501 with the LSD scaling model (Lifton et al., 2014) and the Lifton (2016) geomagnetic database. Both  
1502 calculations rely on the ERA40 atmospheric database (Uppala et al., 2005). This comparison  
1503 demonstrates that our results show little dependence on the scaling procedure. The Lm scaling tends to  
1504 produce ages 400 years older than the LSD scaling. Given the uncertainties on the measurements, this  
1505 difference indicates that 90% of the computed ages are compatible within  $1\sigma$ . For the other 10%, the  
1506 average  $1\sigma$  incompatibility is 100 years. Hence, the CRE ages have very limited model dependence,  
1507 underlying the robustness of the reported glacial chronologies.

1508 *Figure S5. Comparison between two scaling procedures to compute CRE ages with the CREp online*  
1509 *calculator (<https://crep.otelo.univ-lorraine.fr>). For this study, we used the Lm scaling model (Balco et*  
1510 *al., 2008) and the geomagnetic database of Muscheler et al. (2005). We compare our results to those*  
1511 *obtained using the LSD scaling model (Lifton et al., 2014) and the geomagnetic data compiled by Lifton*  
1512 *(2016). We used the spatialized atmosphere ERA40 (Uppala et al., 2005) for both calculations*

1514 **S.6. Illustration of the Bayesian filtering process on the age data**

1515 Figure S6 schematically illustrates how stratigraphic relations between moraines are used to  
1516 filter the age PDFs.
