Abstract

Sustainable carbon materials have been synthesised by use of inexpensive natural precursors, tannin and sucrose, mixed in aqueous solution in various proportions (from 0:1 to 1:0), and then submitted to hydrothermal carbonisation (HTC) at various pH (from 2 to 8) and temperatures (160, 180 or 200°C). The resultant hydrochars were finally pyrolysed at 900°C under nitrogen flow to produce highly porous carbon materials with BET areas as high as 810 m²/g without activation. The effects of the initial tannin/sucrose weight ratios and of the HTC conditions were investigated in terms of final particle size (from 1 to 10 µm), carbon yield (from 30 to 45%), composition (C from 88 to 93 wt. %; O from 6 to 10 wt. %), surface chemistry (C from 88 to 98 at. %; O from 2 to 12 at. %) and porous texture (NLDFT surface areas and micropore volumes from 840 to 1420 m²/g and from 0.23 to 032 cm³/g, respectively). All these parameters were discussed and correlated with the electrochemical properties of the same materials. Special attention was paid to the separate roles of porosity and surface chemistry, and on the reversibility of the electrochemical reactions.

Keywords: Tannin; Sucrose; Hydrothermal Carbonisation; Sustainable Carbons; Supercapacitor electrodes.

1. Introduction

Carbon materials are applied to several fields of paramount importance such as catalysis, water and air depollution, and energy storage and conversion such as secondary batteries or supercapacitors. The production of “sustainable carbon materials” from inexpensive carbon sources including lignocellulosic biomass or other by-products contained in food/agricultural waste, is of major importance nowadays. One way of achieving this target and producing functionalised carbon materials is applying hydrothermal carbonisation (HTC) as a low-cost, scalable, and industrially attractive first step of carbonisation prior to pyrolysis (Antonietti and Titirici, 2010; Celzard et al., 2012; Hu et al., 2010). HTC maintains high oxygen content and allows the functionalisation of the resultant materials without the need of additional chemical reagents (Unur, 2013). The use of moderate temperature and pressure conditions are fundamental for the onset of several reactions to which carbohydrates are submitted such as hydrolysis, dehydration, condensation, aromatisation and polymerisation (Sevilla and Fuertes, 2009). An insoluble black solid that contains higher carbon content than in the original material is obtained, and then a second-step of pyrolysis at 900°C can be applied for increasing the electrical conductivity and improving the textural properties of the final materials.

HTC has been applied to a broad range of carbohydrates and biomass: rice grains, oak leaves, pine needles (Titirici et al., 2007), microalgae (Falco et al., 2012) and prawn shells (White et al., 2009). Mimosa tannin has also been submitted to HTC. Mimosa tannin is a phenolic material that has been used for the production of several materials such as resins/adhesives (Pizzi, 1994), foams (Tondi et al., 2009; Letellier et al., 2017), gels (Szcurek et al., 2011a, 2011b) and recently N-doped carbon materials (Braghiroli et al., 2012, 2015a). This is explained by the fact that such condensed (flavonoid) tannins are quite reactive in the presence of aldehydes (e.g. formaldehyde), and another advantage is that they

can auto-condensate, especially when heated or in presence of strong mineral acids (Pizzi, 1983). Fig. 1 shows the main flavonoid structure of the robinetinidol unit (resorcinol A-ring and pyrogallol B-ring) which constitutes approximately 70% of Mimosa tannin extract (Bate-Smith, 1962; Pizzi, 1983; Hemingway et al., 1989; Pizzi, 1994).

Figure 1

Various carbonaceous microspheres were obtained after tannin HTC, depending on temperature, reaction time and tannin concentration, and their production was found to obey a first-order kinetics with an activation energy of 91 kJ mol^{-1} (Braghiroli et al., 2014). The mechanism of microspheres formation proceeds by nucleation, leading to a high number of small particles, followed by growth and coalescence, leading to bigger particles of lower surface area. The hydrochar yield investigated as a function of pH was found to increase from 64.4 % at unmodified pH (around 4.2 for the aqueous tannin solution) to 86.7 % when the pH was decreased to 1. The pH also influenced the morphology and the texture of the hydrochars, those prepared at non-modified pH being powders, whereas those obtained at low pH being stiff monoliths presenting a higher surface area, up to $800 \text{ m}^2 \text{ g}^{-1}$ after pyrolysis at 900°C . But in all cases, the micropore size distributions were the same (Braghiroli et al., 2015b).

Concerning sugars, Wang et al. (2001) submitted a sucrose solution (1.5 mol L^{-1}) to HTC at 190°C during 5h to produce carbonaceous microspheres with an average diameter of $5 \mu\text{m}$ and a BET area as high as $400 \text{ m}^2 \text{ g}^{-1}$ after subsequent pyrolysis at 1000°C . Then, Sevilla and Fuertes (2009) studied the hydrochars obtained after HTC of several saccharides in different conditions of temperature ($170\text{-}240^\circ\text{C}$) and reaction time (0.5-15h) concluding that they presented a core-shell structure consisting of a hydrophobic core and a hydrophilic shell containing reactive oxygenated functional groups. Next, Falco et al. (2012) observed the effect of adding glucose to microalgae organisms submitted to HTC, and found that such

strategy allowed incorporating nitrogen in the final carbon matrix and also increasing the carbon yield from 18 to 47.5%.

In the present study, we used condensed tannin combined with commercial sugar (sucrose) to see the effects of such mixture on the preparation of carbon materials. Sucrose was selected because it is a commercial product, readily available and not expensive but also for comparison purposes with previous studies (Wang et al., 2001; Sevilla and Fuertes, 2009). Various kinds of microspheres were seen by electron microscopy, depending on temperature, pH, and sucrose / tannin ratio. After a subsequent thermal treatment at 900°C, the final carbon materials presented developed textural properties especially at low pH. To understand better the influence of the various chemical and structural characteristics of the present carbons, some of them were tested as electrode materials and the reversibility of the oxygen groups' reactions in acidic electrolyte was studied. Such electrochemical studies allowed separating the roles of the materials' features, and suggesting how to improve further their capacitance if we were to start developing supercapacitor electrodes.

2. Materials and methods

2.1 Raw materials

Mimosa tannin, kindly supplied by SilvaChimica, was used in this study. The extraction process and the composition of the tannin extract was described elsewhere (Braghiroli et al., 2014).

2.2 Hydrothermal treatment

In a typical synthesis, 2.0 g of either tannin (T) alone, sucrose (S) alone, or tannin-sucrose mixture, were dissolved in 16.0 g of water, put inside a glass vial and then into a Teflon-lined autoclave for 24h installed in an oven preheated at 180°C. Different conditions of hydrothermal carbonisation (HTC) were studied, using various fractions of sucrose: 0, 25, 50,

75 and 100 wt. %. The addition of sucrose changed the pH from 4.2 (100% T) to 8 (100% S). The resultant materials were called HsStT180_u, s and t being the percentages of sucrose and tannin, respectively, and u meaning unmodified pH. A second series of samples was prepared by fixing the pH at 2 by use of pTSA. Those materials were labelled HsStT180_2. The HTC temperatures were also varied, 160 or 200°C, and the corresponding samples were labelled HsStT160_u or HsStT200_u for unmodified pH experiments.

In all cases, the filtrates were recovered, washed with water, and then dried in a vacuum oven at 80°C. Pyrolysis was carried out under nitrogen flow in a tubular furnace heated at 1°C min⁻¹ up to 900°C, and this temperature was hold for 3h. Pristine tannin (OS100T) was also carbonised in the same conditions and labelled C0S100T. In order to distinguish carbon materials from hydrochars, we added a 'C' at the beginning of the label; for instance, the sample H100T180_2 became CH100T180_2 after pyrolysis at 900°C.

2.3 Materials characterisation

Scanning electron microscopy (SEM) observations were carried out with a FEI-Quanta 400 apparatus for investigating the morphology of the samples, which were metallised beforehand. A series of images was taken for each sample, and only one was provided here as an example. The purpose was to evaluate the morphology of the samples and to observe general trends in the particle size, depending on the preparation conditions.

Pore texture parameters were obtained by krypton adsorption at -196°C for organic, or non-porous samples obtained after HTC, and by nitrogen adsorption at -196°C for pyrolysed materials, using a ASAP 2020 automatic apparatus (Micromeritics) in both cases. CO₂ adsorption at 0°C was also carried out on pyrolysed samples using a Micromeritics ASAP 2420 apparatus. The following parameters were determined: NLDFT surface area, S_{NLDFT} (m² g⁻¹); BET area, A_{BET} (m² g⁻¹); total pore volume, $V_{0.97}$ (cm³ g⁻¹); micropore volumes, $V_{DR,N2}$

and V_{DR,CO_2} ($\text{cm}^3 \text{ g}^{-1}$), from the N_2 or CO_2 adsorption isotherms; micropore volume, $V_{\mu,NLDFT}$ ($\text{cm}^3 \text{ g}^{-1}$), by applying the 2D- NLDFT-HS to both CO_2 and N_2 adsorption isotherms; and mesopore volume, V_{mes} ($\text{cm}^3 \text{ g}^{-1}$), calculated as the difference $V_{0.97} - V_{DR,N_2}$. The pore size distributions (PSDs) were calculated by applying the 2D-NLDFT-HS method to both CO_2 and N_2 adsorption isotherms. More details are given elsewhere (Schaefer et al., 2016).

Ultimate analyses of samples were carried out in a CHONS elemental analyser (Vario El cube, Elementar) as reported elsewhere (Celzard et al., 2019). Temperature-Programmed Desorption (TPD) experiments were performed with a custom-built set-up, consisting of a tubular quartz reactor placed inside an electric furnace. In a typical experiment, the sample was heated up to 1100°C in Ar atmosphere at a heating rate of $10^\circ\text{C min}^{-1}$. The amounts of CO and CO_2 were determined as reported elsewhere (Tellez-Juárez et al., 2014).

X-ray photoelectron spectroscopy (XPS) results were recorded with an ESCAPlus OMICROM system equipped with a hemispherical electron energy analyser. Measurements were carried out as reported elsewhere (Sanchez-Sanchez et al., 2018).

Electrochemical characterisation was performed with a Biologic VMP3 multi-potentiostat. The carbon electrodes were prepared by spreading onto a graphite foil a paste ($\sim 15 \text{ mg cm}^{-2}$) made of the carbon material mixed with polytetrafluoroethylene (PTFE) binder and carbon black in the weight percent ratio of 85:10:5. The resulting electrodes were then pressed at 5 MPa and impregnated by $1 \text{ mol L}^{-1} \text{ H}_2\text{SO}_4$ electrolyte during 48 hours. Cyclic voltammetry (CV) tests were carried out at different scan rates between 0.5 and 100 mV s^{-1} and within the potential window of 0 – 0.8 V in a three-electrode cell, using a platinum gauze as the counter electrode and a saturated calomel electrode (SCE) as the reference one. The specific capacitance (C , F g^{-1}) was calculated from the CV curves according to Eq. (1):

$$C = (\int I dV) / (s \Delta V m) \quad (1)$$

167 where I (A) is the current, s (V s^{-1}) is the scan rate, ΔV (V) is the potential window and m (g)
168 is the mass of carbon in the electrode.

3. Results and discussion

3.1 Carbon yields and morphologies

To study the effects of the pH on the tannin / sucrose solution submitted to HTC, the same weight (1 g) of sucrose and tannin was used. Table 1 shows the main characteristics of these hydrochars (H50S50T) at different pH ranging from 1 to unmodified (4.2). Unlike H0S100T (100% tannin submitted to HTC - see Fig. 2), submitting 50S50T to HTC at different pH did not produce any change in the HTC yield. Being at the level of 61.5 ± 1.5 wt. %, the HTC yield of 50S50T was also always much lower than that of H0S100T. The A_{BET} values (around $1 \text{ m}^2 \text{ g}^{-1}$) were almost the same for 0S100T, H0S100T and H50S50T, considering the intrinsic uncertainties of adsorption techniques as soon as very low surface areas are concerned. Therefore, it can be concluded that, after HTC, the materials were not porous.

After a second thermal treatment at 900°C , A_{BET} increased from $471 \text{ m}^2 \text{ g}^{-1}$ for tannin directly pyrolysed (C0S100T) to $639 \text{ m}^2 \text{ g}^{-1}$ for CH50S50T 180_u (i.e., at unmodified pH), and even up to $809 \text{ m}^2 \text{ g}^{-1}$ for CH50S50T 180_1 (i.e., at pH 1). The increase of A_{BET} was also observed for the 100% tannin material (CH0S100T) having been submitted to HTC at low pH. Fig. 2 summarises the results of HTC yield and A_{BET} of all these hydrochars H0S100T and CH0S100T (already demonstrated in (Braghiroli et al., 2015b)) and H50S50T and CH50S50T at pH values ranging from 4 to 1. The results on pure tannin are presented here for the sake of comparison to study the effect of sucrose addition.

Figure 2

It has already been mentioned that heating tannin in the presence of strong mineral acids favours its condensation/polymerisation reactions by different possible ways to form “phlobaphenes” or “tanner’s reds”, which are high-molecular weight, insoluble molecules (Pizzi, 1983; Braghiroli et al., 2015a). Tannin treated after HTC at 180°C was shown to have

a structure similar to that of flavonoid tannin (see [Fig. 1](#)), but presents a much higher level of polymerisation, mainly through the opening of the heterocyclic C2–ring and subsequent partial condensation between C2 (open) to C6 or C8, and partly through some auto-condensation C4 to C6 and C8 (Braghiroli et al., 2015a).

On the other hand, sucrose submitted to HTC undergoes hydrolysis that produces glucose and fructose, which decompose into hydroxymethylfurfural (HMF) as the main dehydration product, plus aldehydes (formaldehyde, pyruvaldehyde, etc.) and organic acids (acetic, formic, levulinic acids, etc.), hence producing a rapid pH change from 8 to 3 as shown in the literature (Antal et al., 1990; Ulbricht, 1984; Asghari and Yoshida, 2006). Glucose and fructose can also undergo polymerisation and condensation reactions as reported elsewhere (Antal et al., 1990; Kabyemela et al., 1997; Luijkx et al., 1995; Sevilla and Fuertes, 2009). Titirici et al. (2008) observed that the morphologies and chemical structures of carbons obtained from sucrose are directly related to those of carbons obtained from pure furan. It was also found that such intermediate molecules derived from saccharide dehydration as mentioned above coexist with furans and account for the observed changes of particle size, textural properties and particles aggregation.

When both materials (tannin and sucrose) coexist, we can assume that several reactive germs are obtained through hydrolysis of sucrose submitted to HTC. SEM photos show that the average microsphere diameter was reduced from 10 μm for H0S100T (see [Fig. 3a](#)) to 2-5 μm by simple addition of sucrose (see [Fig. 3c](#)) for H50S50T, whereas 100% sucrose produced spheres of average size 1-2 μm (see [Fig. 3b](#)). This finding suggests that sucrose reacts faster than tannin, producing more germs and, consequently, smaller spheres are obtained (see [Fig. 3c](#)).

217 **Table 1:** Textural properties and elemental analysis obtained for materials 50S50T after HTC and subsequent pyrolysis made at different pH.

	Sample	Yield (wt. %)			Textural Properties						Elemental Analysis (wt. %)

218

A similar effect was found by decreasing the pH down to 2. Small spherical particles of around 2 μm arranged in a necklace structure were indeed obtained in carbons based on either pure tannin (see Fig. 3d) or tannin-sucrose mixture (compare Fig. 3c, 3f, 3g and 3h) submitted to HTC at pH 2. No changes in particle diameter were observed, as their size was nearly constant around 2 μm , irrespective to the HTC temperature: 160, 180 or 200°C. This finding at lower pH is different from what was formerly observed for H0S100T at unchanged pH and 160°C, for which irregular spheres were found, indicating that HTC reaction was not finished. By increasing the HTC temperature from 180 to 200°C, bigger and rounded spheres were observed (Braghiroli et al., 2014).

Figs. 3b and 3e show SEM pictures of carbon materials derived from 100S0T submitted to HTC at unchanged pH (pH around 4) or at pH 2. HTC of 100S0T at unchanged pH produced mostly monodisperse spherical particles having a size of approximately 1 μm , in agreement with other authors (Titirici et al., 2008; Sevilla and Fuertes, 2009). However, sucrose hydrolysis at pH 2 produced bigger spheres of around 5-10 μm . Zhao et al. (2013) observed the effect of the acidic pH on the formation mechanism of carbon spheres when submitting cellulose to HTC. The compounds obtained from cellulose hydrolysis rapidly react with H^+ present in the system through dehydration and polymerisation reactions and lead to hydrochar nucleation. Besides that, they concluded that the acid concentration in the HTC system could also control the shape and the diameter of the carbon spheres.

Figure 3

Table S1 shows the main characteristics of hydrochars and carbon materials prepared with 50% of sucrose (50S50T) at different HTC temperatures (160, 180 and 200°C) and different pH. Some of these results are summarised in Fig. 4 including the total carbon yield and the A_{BET} as a function of HTC temperature at unchanged pH or at pH 2. The HTC yield was around 60% irrespective to the temperature or the pH. After pyrolysis, the total carbon yield

appears to be constant, around 30%, whatever the HTC temperature or the pH used beforehand. In the same way, A_{BET} did not change with HTC temperature but was higher for samples prepared at pH 2. Indeed, carbons prepared from hydrochars obtained at pH 2 presented an A_{BET} of $735 \pm 32 \text{ m}^2 \text{ g}^{-1}$, while those prepared at unchanged pH had an A_{BET} of $629 \pm 10 \text{ m}^2 \text{ g}^{-1}$.

Figure 4

In order to study the effect of the percentage of sucrose on the hydrochar characteristics, hydrochars based on various proportions of tannin and sucrose were prepared at unchanged pH and at pH 2, summarised in Table S2. We can observe by SEM photos in Fig. 5a to 5c that, by increasing the weight fraction of sucrose from 25 to 100% at unchanged pH, the sphere diameter decreased from around 10 to 2 μm and they became more individualised and more monodispersed. Polydispersity and higher particle size thus appear to be a consequence of tannin presence in the system at unchanged pH. In the literature, changes of particles morphology produced by mixing two carbon precursors submitted to HTC were also evidenced for microalgae in the presence of glucose added in a mass ratio of 1:1. In that case, the final particles morphology was that of pure glucose but with a double higher average diameter, passing from 1 to 2 μm (Falco et al., 2012). Coming back to the present situation, the effect of adding sucrose at pH 2 was opposite to that observed at unchanged pH. With the addition of sucrose at lower pH, the average sphere diameter increased from 1-2 μm to 2-3 μm and finally to around 5-10 μm when the proportion of sucrose increased from 25% (Fig. 5d), to 75% (Fig. 5d) until 100% (Fig. 5f), respectively.

Figure 5

Fig. 6a shows the HTC yield of all materials at different proportions of sucrose / tannin and at two pH, unchanged and 2. The dotted lines represent the theoretical yield calculated from

the experimental yields of 0S100T and 100S0T (e.g. for 75S25T we have $Y_{HTC, 75S25T} = (75 \times Y_{HTC, 100S0T} / 100 + 25 \times Y_{HTC, 0S100T} / 100)$), in order to observe any synergetic effect between tannin and sucrose during HTC. At pH 2, the experimental HTC yield was very similar to the expected value, so we can conclude that there is no apparent interaction between sucrose and tannin regarding the yield. Acidic pH accelerates HTC reactions, both for sucrose and tannin precursors (Lee et al., 1999; Kim et al., 2001; Trajano and Wyman, 2013) and no differences were observed. At unmodified pH, experimental HTC yield of tannin-sucrose mixtures were higher than those theoretically calculated, suggesting that HTC products of sucrose and tannin interact with each other. At pH around 4, sucrose yielded more solid materials. Its higher HTC kinetics compared to tannin led to more germs with a resulting lower particle size and an enhanced HTC yield. Since at pH 2 the experimental HTC yield was the same as calculated, it can be assumed that a low pH promotes fast reactions to liquid products (Lee et al., 1999; Kim et al., 2001; Trajano and Wyman, 2013) that do not interact with tannin.

Figure 6

3.2 Porous texture and composition

Fig 6b shows the BET area of the same hydrochars as in Fig. 6a but after pyrolysis at 900°C. As a general remark, the addition of sucrose to tannin slightly increased A_{BET} . The highest A_{BET} was found for the mixture 50S50T at both pH, but the main effect on the increase of surface area was due to the pH reduction. Fig. 7 shows that the product $A_{BET} \times$ total carbon yield increased with the total carbon yield. This effect is opposite to what is obviously found for carbon activation, whether physical or chemical, which produces higher surface area when the carbon yield decreases, i.e., when the burn-off increases. Besides, by increasing the proportion of tannin mixed with sucrose in HTC conditions, an increase of the total carbon yield can be seen. However, the highest A_{BET} was obtained at equal proportion (50:50) of T and S at pH 2. Such increase of surface area, from 476 to 791 m² g⁻¹, cannot be explained by

the decrease of particle diameter from 10 μm (CH0S100T180_u) to approximately 2 μm (CH50S50T180_2), which accounts for less than 1% of the measured A_{BET} . As previously discussed in Braghiroli et al. (2015b), the decrease of particle size might facilitate the evolution of volatile matter and then the development of textural properties.

Figure 7

All materials were found to be microporous, given their Type I nitrogen isotherms at -196°C, having a vertical part at low relative pressure P/P_0 and an almost horizontal part from $P/P_0 = 0.02$ to 1 as shown in Fig. 8a for CH50S50T180_2 and CH50S50T180_u. The pore size distribution calculated by NLDFT is presented in Fig. 8b for the same samples; CH50S50T180_2 had some porosity in the mesopore range (between 2 and 10 nm), whereas CH50S50T180_u presented an entirely microporous structure. The isotherm of sample prepared at pH 2 presented a slight slope showing the presence of pores broader than 2 nm. Most of the carbohydrates submitted to HTC needed a second thermal treatment, at higher temperature, to increase the porosity of the resultant carbon materials. However, glucose after HTC and subsequent pyrolysis at 900°C was poorly porous and had low surface areas, around 30-50 $\text{m}^2 \text{g}^{-1}$ (Zhao et al., 2010). Thanks to the reactivity of tannins in hydrothermal conditions and posterior pyrolysis at 900°C, highly porous material were obtained ($A_{\text{BET}} > 600 \text{ m}^2 \text{g}^{-1}$) confirming its potential as precursor for the production of porous carbons.

Figure 8

As for the chemical composition, Fig. 9a shows the van Krevelen diagram for all hydrochars and carbon materials prepared from tannin and sucrose at different pH and HTC temperatures (160, 180 and 200°C). The main arrow (from 100S0T to HTC_900°C, i.e., from pure sucrose to all carbons obtained by HTC followed by pyrolysis at 900°C) indicates the loss of oxygen and hydrogen, and therefore the increase of carbon content after both thermal treatments (HTC at 160-200°C and pyrolysis at 900°C) (van Krevelen, 1950). The percentage

of carbon increased after HTC and obviously even more after pyrolysis. After HTC, samples prepared at unmodified pH retained more oxygen, 30-36 wt. %, than those prepared at pH 2, 28-33 wt. %. After pyrolysis at 900°C, carbon derived from hydrochars prepared at unmodified pH retained more oxygen, 6-10 wt. %, than those prepared at pH 2, 3-6 wt. %.

[Fig. 9b](#) shows the total amounts of CO and CO₂ gases in mmol g⁻¹ that have been lost during a thermal treatment (TPD analysis) up to 1100°C for materials at different T/S proportions. CO₂ derives from precursors comprising carboxylic acids, lactones and anhydride groups, and CO derives from quinonic and phenolic groups (Figueiredo et al., 1999). Boudouard equilibrium also takes place, modifying the CO/CO₂ ratio. The total amount of released gases (CO + CO₂) was higher for materials HsStT_u prepared without pH modification (0.065-0.075 mmol g⁻¹) than for HsStT_2 prepared at pH 2 (0.036-0.052 mmol g⁻¹). This is in good agreement with their higher amount of oxygen, 32.4-36.3 wt. %, compared to 30.6-32.7 wt. % in HsStT_2 materials, measured by EA ([Table 1](#) and [Table S1](#)). Indeed, tannin in the presence of strong acids undergoes dehydration and condensation reactions (Pizzi, 1983; Braghiroli et al., 2015a), which might have reduced the amount of oxygen in hydrochars.

Figure 9

Surface atomic concentrations obtained by XPS and contributions to the C1s, O1s and N1s high-resolution spectra of the hydrochars and carbon materials are collected in [Table 2](#) and in [Fig. S1](#) to [S6](#) of the Supporting Information section. Tannin-derived hydrochars presented high oxygen surface concentrations, between 12.6 and 19.6 at. %, but low nitrogen surface concentrations, between 0.3 and 1.3 at. %. No influence of the pH of the medium on the oxygen surface concentration of the hydrochars was evidenced. Sucrose-derived hydrochars contained 17.9 at. % surface oxygen, and a small concentration of nitrogen, 0.3 at. %, in agreement with the chemical composition of sucrose and with the presence of amino-acids

coming from the raw sugar beet. As expected, the oxygen concentration of the hydrochars significantly decreased after pyrolysis, and the resultant carbons exhibited oxygen surface concentrations between 2.3 and 11.7 at. %. The concentration of nitrogen varied in the range 0.40 – 1.7 at. %, being only present at the surface of carbons prepared at pH higher than 3.

Deconvolution of the high-resolution XPS spectra allowed identifying chemical bonds that are characteristic of specific functional groups. C1s high-resolution spectra for all samples exhibited an asymmetric peak centred on binding energies (BE) of 284.4 – 284.5 eV (Table 2, and Fig. S1 and S4 in the Supporting Information section). Except for H50S50T180_3, the deconvolution of the C1s high-resolution profiles gave rise to five peaks, CI to CV, with binding energies (BE) between 284.4 and 290.6 eV: CI is assigned to Csp² in hydrocarbons, aromatics and aliphatics; CII is associated with Csp³ and C-O single bonds associated with ethers, phenols and anhydrides; CIII is assigned to C=O double bonds in carbonyls and quinones; CIV corresponds to C-O single bonds in carboxylic groups; and CV is related to plasmon losses or shake-up π - π satellites. In the case of H50S50T180_3, an additional peak C* appeared at an unusually low BE, 283.6 eV. This peak may be associated to pre-graphite-like C in highly aromatic materials (Cagniant et al., 1998; Weckhuysen et al., 1998).

The O1s high-resolution spectra of the hydrochars presented, in general, two oxygen contributions (Table 2): O1, assigned to C=O double bonds in quinone-type groups, carbonyls and carboxylic acids; and O2, related to -OH bonds in phenols, C-O-C in ether groups and C=O bonds in ester and anhydride groups. The O1s high-resolution spectra exhibited generally O1, O2 and O3 contributions, O3 being assigned to chemisorbed oxygen, single C-O bonds in esters and anhydrides, and C-O bonds in carboxylic groups and/or water.

Finally, the deconvolution of the N1s high-resolution spectra was only possible for samples with surface nitrogen concentrations higher than 1 at. %. Curve fitting was not possible for the N1s high-resolution spectrum of H50S50T180_3 hydrochar, due to the low

area of the peak. N1s high-resolution spectra of both hydrochars and carbons exhibited three contributions assigned to three types of functional groups: N6, related to pyridinic nitrogen; N5, related to pyrrolic nitrogen; and NQ, assigned to quaternary nitrogen (Briggs, 2005; Dongil et al., 2011; Weidenthaler et al., 2006).

In general, pyrolysis decreased the relative concentrations of the groups related to CII and OII, while increasing the relative amounts of the groups related to the peaks CIII, CIV and OI. This finding means that the concentration of ethers, phenols, esters and anhydrides decreased whereas the concentration of quinone-type groups, carbonyls and carboxylic acids increased as a consequence of pyrolysis.

Concerning the structure of the carbons obtained by pyrolysis at 900°C of the aforementioned hydrochars, it can be added that none of these materials are graphitic, as evidenced by their XRD patterns showing very broad and poorly defined (002) and (10 $\bar{l}$) bands (see for instance (Tondi et al., 2009) and the supplementary information of (Celzard et al., 2019) for typical patterns of carbons based on tannin and tannin-sugar produced at 900°C). The corresponding Raman spectra demonstrated the same, but also that these materials are not graphitisable either, unless transition metals are added as graphitisation catalyst, which was not the case here. Typical Raman spectra of carbons based on tannin and tannin-sugar produced at 900°C can be found elsewhere (Celzard et al., 2019; Braghiroli et al., 2017), and prove that the present materials are definitely highly disordered, i.e. very poorly crystallised, carbons.

Concerning the morphology, carbon spheres have a wide range of applications, depending on their diameter, pore texture and surface chemistry. For example, they can be used in batteries (Park et al., 2018) or supercapacitors (Zhou et al., 2015), as catalysts (Frusteri et al., 2016, Maciá- Agulló et al., 2010) or even as boosters to produce pure water as we reported recently (Celzard et al., 2019).

393 **Table 2.** Atomic surface concentrations of C, N and O, and contributions to the C1s, O1s and N1s high-resolution XPS spectra of the materials in
394 terms of peak area fraction (%) at given binding energies (BE, eV).

3.3 Electrochemical properties

Among the carbon materials, C0S100T, CH50S50T180_1 and CH50S50T180_u were selected for studying their electrochemical behaviour. With respect to porous texture, C0S100T and CH50S50T180_1 are among the materials having the highest micropore volumes, although their PSDs are clearly not the same, as suggested by the data of Table 1. With respect to surface chemistry, the most remarkable difference in their surface chemistry is that CH50S50T180_u exhibited higher surface oxygen content than the other two carbons, and that CH50S50T180_1 exhibited higher relative concentrations of quinone and carbonyl groups (OI peak). The latter are the most electroactive oxygen functionalities in acidic electrolytes (Inagaki et al., 2010). Choosing such materials for electrochemical tests was therefore supposed to clarify the understanding of these new carbon materials.

At the lowest scan rate of 0.5 mV s^{-1} , cyclic voltammetry (CV) curves of C0S100T and CH50S50T180_1 exhibited more defined peaks of both anodic and cathodic currents than CH50S50T180_u despite possessing a lower concentration of oxygen on their surfaces (Fig. 10a). The presence of redox peaks is due to a contribution of the surface oxygen groups to the total capacitance of the electrodes by a pseudocapacitance mechanism. Even at this low scan rate of 0.5 mV s^{-1} , CV curves of CH50S50T180_u exhibited a highly distorted profile with respect to the rectangular shape of an ideal electric-double layer capacitor (ELDC). This fact may indicate the existence of kinetic limitations for ion transport, and agrees with the highly microporous texture of the carbon, whose percentage of narrow porosity (width $< 0.7 \text{ nm}$) was the highest of the three materials, 84.0%, and whose percentage of mesoporosity was the lowest one, 0.0%. At the relatively low scan rate of 10 mV s^{-1} , the shape of the CV curves of all the materials clearly deviated from the rectangular one, and no clear peak could be seen (Fig. 10b). This suggests that the behaviour of the supercapacitor electrodes becomes less

capacitive and more resistive, due to kinetic limitations, and that pseudocapacitance contribution is negligible, respectively (McDonough et al., 2012).

The studied electrode materials yielded similar values of specific capacitance in the entire range of investigated scan rates. At the lowest scan rate of 0.5 mV s^{-1} , specific capacitances of 51, 57 and 58 F g^{-1} were exhibited by C0S100T, CH50S50T180_1 and CH50S50T180_u, respectively (Fig. 10c). These capacitance values progressively decreased when the scan rate increased, due to the increasing resistance to diffusion of electrolyte ions into the pores. At 100 mV s^{-1} scan rate, the specific capacitance was 15 F g^{-1} for all the materials (Fig. 10c), which corresponds to capacitance retentions of 30.4, 26.6 and 26.3% for C0S100T, CH50S50T180_1 and CH50S50T180_u, respectively (Fig. 10d). The lower capacitance retention of CH50S50T180_1 and CH50S50T180_u compared to C0S100T indicates the existence of more important kinetic limitations at increasing scan rates due to their high fractions of narrow porosity, 71.4 and 84.0%, respectively. The CV results agree with a previous study on molasses-derived carbons, in which the materials prepared by HTC exhibited, in the studied potential window, lower capacitances than those that were directly pyrolysed, mainly due to their narrow porosities and low electrical conductivities (Sanchez-Sanchez et al., 2016).

Figure 10

In order to determine the pseudocapacitance contribution to the overall capacitance of the materials, interfacial capacitances at different scan rates, C / S_{NLDFT} , were plotted versus oxygen surface concentrations (Fig. S7a of the Supporting Information section). The interfacial capacitance was calculated by considering S_{NLDFT} instead of A_{BET} , since it has been previously shown that this approach is more appropriate for materials mainly comprising narrow pores, such as in the present case (Sanchez-Sanchez et al., 2016). In general, higher surface oxygen concentrations were not related to higher interfacial capacitances in the entire

range of studied scan rates. This should mean that the pseudocapacitance contribution of the materials is lower than the capacitive contribution, for which the porous texture is the key parameter.

Oxygen functional groups have a great influence on the electrochemical properties of carbon materials (Anjos et al., 2013; Tanaka et al., 2015). Hydroxyl, carbonyl and, especially, quinone groups, have been proved to yield more capacitance than carboxyl, anhydride or lactone groups in acidic aqueous electrolytes thanks to their Faradaic reactions (Inagaki et al., 2010). Redox reactions involving these groups are the following (Oh et al., 2014):

where the symbol $>$ represents the surface of the carbon material. Protons, H^+ , are not only simply adsorbed on the oxygen functional groups, but are involved in the electrochemical reactions.

As a consequence of these Faradaic reactions, redox peaks can appear on the anodic and cathodic branches of the CV curves of the carbon materials. CV curves obtained in a three-electrode cell in $1 \text{ mol L}^{-1} \text{ H}_2\text{SO}_4$ electrolyte, measured at 0.5 mV s^{-1} scan rate and considering the first cycle of cycling, are displayed in Fig. 11. These curves exhibited two redox processes associated to peaks 1 and 2 appearing in the anodic and cathodic branches, which are represented by the “ox” and “red” superscript, and are defined by two parameters:

(i) peak current, I_p , which is the current at the maximum of the peak; and (ii) peak potential, E_p , which is the potential at the maximum of the peak (Fig. 11a, 11c and 11e).

Figure 11

For the samples C0S100T and CH50S50T180_1, no second anodic peak, $I_{p,2}^{ox}$, was seen, indicating the irreversibility of the associated redox process. In contrast, the first peak could be clearly observed both in the anodic and cathodic branches and appeared in the five cycles studied at scan rates from 0.5 to 5 mV s⁻¹ for C0S100T, and from 0.5 to 2 mV s⁻¹ for CH50S50T180_1 and CH50S50T180_u. This suggests that the associated redox system may be quasi-reversible in the aforementioned scan rate intervals. The highly distorted CV curves with respect to the expected rectangular shape of an ideal electric-double layer capacitor at scan rates above 2 or 5 mV s⁻¹ did not allow differentiating clear redox peaks. Therefore, the reversibility of the redox system 1 was studied up to a maximum scan rate of 5 mV s⁻¹. The formal potentials of peak 1 vs SCE reference, calculated as $E^0 = 1/2 (E_{p,1}^{ox} + E_{p,1}^{red})$, were 0.425, 0.424 and 0.444 V for C0S100T, CH50S50T180_1 and CH50S50T180_u, respectively. The reversible character of the redox process was evaluated through the following criteria:

1) *Peak separation*, $\Delta E = E_{p,1}^{ox} - E_{p,1}^{red} \leq 0.059 / n$, where $E_{p,1}^{ox}$ and $E_{p,1}^{red}$ (V) are the maxima of the anodic and cathodic peaks, respectively, and n is the number of transferred electrons: Considering the transfer of 1 electron, the peak separation was lower than 0.059 V at the lowest scan rate of 0.5 mV s⁻¹ for the three materials, suggesting the reversibility of the redox process. ΔE generally increased above 0.059 V as the cycle number increased, which indicates that the redox process was progressively less reversible due to the gradual transformation of surface groups into non-electroactive species. However, ΔE was progressively lower than 0.059 V at the scan rate of 0.5 mV s⁻¹ for the sample C0S100T, suggesting a higher reversibility of the redox process (Fig. 11b, 11d and 11f). This can be

explained by the improvement of the surface wettability during the cycling process, which facilitates the contact between the surface functionalities and the electrolyte ions, so that redox reactions are easier to occur, and also by the higher fraction of pores involved in the materials as the cycling process goes on (Jiang et al., 2013). Varying the scan rate in cyclic voltammetry allows varying the diffusion layer thickness, thus enabling the control of the electrochemical process either by electron transfer or by mass transport. The diffusion layer is thicker at low scan rates, and thinner as the scan rate increases. Electrochemical processes reflect the competition between reactions at the electrodes and diffusion, so that faster scan rates favour electrochemical irreversibility, which is controlled by the electron transfer rate, and the peak potentials are thus shifted. This trend is clearly observed in Fig. S7b of the Supporting Information section, which shows the progressive separation of maxima of the peaks associated to the redox process 1 at increasing scan rates from 0.5 to 2 mV s⁻¹ for a representative sample, C0S100T (McDonough et al., 2012). When the peak potentials remain constant with increasing scan rates, the involved redox process is reversible. Fig. 12b, 12d and 12f show the progressive increase of the peak potentials of the studied samples, $E_p^{ox,red}$, at increasing scan rates, $\ln s$, indicating the quasi-reversibility of the involved redox system (Gómez et al., 2011).

2) *Ratio of anodic to cathodic currents, $I_{p,1}^{ox} / I_{p,1}^{red} \approx 1$, where $I_{p,1}^{ox}$ and $I_{p,1}^{red}$ (A) are the currents at the maximum of the anodic and cathodic peaks, respectively:* When the peak currents, I_p , for the oxidation and reduction reactions are the same, i.e., $I_{p,1}^{ox} / I_{p,1}^{red} = 1$, the redox process is reversible (Bard and Faulkner, 2001). The current ratios of the studied samples at scan rates ranging from 0.5 to 2 mV s⁻¹ were 0.98 ± 0.04 , which indicates the quasi-reversibility of the redox process.

3) *Scan rate dependence of peak current, $I_p^{ox,red} \propto s^{1/2}$, where $I_p^{ox,red}$ (A) is the current at the maximum of the anodic or the cathodic peaks and $s^{1/2}$ (V^{1/2} s^{-1/2}) is the square root of the*

scan rate: A linear relationship between $I_p^{ox,red}$ and $s^{1/2}$ indicates that the redox process is quasi-reversible (Gómez et al., 2011) As shown in Fig. 12a, 12b and 12c, $I_p^{ox,red}$ versus $s^{1/2}$ leads to linear relationships for the studied samples, with determination coefficients close to 1, thus indicating that the concerned redox processes are quasi-reversible. From these linear relationships and applying the Randles-Sevcik equation (Eq. 2), the diffusion coefficients, D_0 , of the processes were calculated (McDonough et al., 2012). The Randles-Sevcik equation reads:

$$I_p = 0.4463 n F A C [(F D_0 s) / (R T)]^{1/2} \quad (2)$$

where I_p (A) is the peak current, n is the number of electrons transferred in the reaction, F (C mol⁻¹) is the Faraday constant, A (cm²) is the electrode area, C (mol L⁻¹) is the concentration of the diffusing species in the bulk of the electrolyte, D_0 (cm² s⁻¹) is the corresponding diffusion coefficient, s (V s⁻¹) is the scan rate, R (J mol⁻¹ K⁻¹) is the universal gas constant and T (K) is the temperature. Considering that $n = 1$ and $C = 1$ mol L⁻¹ (H₂SO₄), the diffusion coefficients were found to be 1.602×10^{-13} , 1.156×10^{-13} and 6.973×10^{-14} cm² s⁻¹ for C0S100T, C50S50T180_1 and C50S50T180_u, respectively. These values are considerably lower than those obtained for well-established redox processes in other doped carbons used as electrode materials, such as graphene-polyaniline (PANI) nanocomposites or PANI systems alone, suggesting a hindered ion transport (Gómez et al., 2011). Therefore, activation for opening the porosity and developing it further appears necessary for improving the electrochemical performance of these materials. For instance, we have recently shown that CO₂ activation allows increasing the surface area of tannin-derived mesoporous carbons up to nearly 2000 m²/g and maintaining high-rate capability when increasing the current density up to 80 A/g (Castro-Gutiérrez et al., 2019). The same kind of behaviour can therefore be expected with the present samples.

Figure 12

4. Conclusions

Tannin-sucrose blends mixed in various proportions were submitted to hydrothermal carbonisation (HTC) at different pH and temperatures, and then pyrolysed at 900°C under nitrogen flow. Microporous carbon spheres with BET areas as high as 810 m²/g, without further activation, were produced. Adding more sucrose produced microspheres of lower particle size due to the increased amount of germs produced by the HTC of sucrose.

HTC was confirmed to be an interesting low-cost and environment-friendly step to tune the properties of the resultant carbon materials, modifying their porous texture and their chemical composition, and thus broadening the range of their properties and therefore of their applications. The preliminary electrochemical tests reported here were carried out to select the most promising materials for further research. Although the carbon electrodes presented a quasi-reversible redox reaction concerning oxygen groups, their narrow pores hindered transport of electrolyte ions and led to low values of capacitance retention when increasing the current density and the scanning rate. Activation should significantly improve this results, and will be the object of a forthcoming study.

Synthesis and properties of porous carbons based on tannin-sucrose mixtures treated in hydrothermal conditions
Sanchez-Sanchez et al.

Captions of the Figures

Fig. 1: Main flavonoid unit contained in Mimosa tannin extract.

Fig. 2: Changes of HTC yield of H0S100T180 and H50S50T180 hydrochars obtained at different pH, and BET areas of the corresponding carbons after subsequent pyrolysis at 900°C (dashed lines are just guides for the eye).

Fig.3: Typical SEM images of carbon materials (i.e., pyrolysed at 900°C) based on: tannin (CH0S100T) and sucrose (CH100S0T) submitted to HTC at 180°C with, a) and b) unmodified pH and d) and e) pH 2, respectively; based on 50S50T samples submitted to HTC at 180°C with c) unmodified pH and f) pH 2; and finally based on 50S50T samples submitted to HTC at pH 2 g) at 160°C and h) 200°C.

Fig. 4: Total carbon yield and BET area of HTC materials (H50S50T) prepared at different HTC temperatures (160, 180 and 200°C) at unmodified pH and pH 2, and of pyrolysed (900°C) CH50S50T carbons.

Fig. 5: Typical SEM images of carbon materials (i.e., pyrolysed at 900°C) based on sucrose and tannin mixed in proportions ranging from 25-75 to 100-0 (from left to right) and submitted to HTC at unmodified pH (a, b, c) and pH 2 (d, e, f).

Fig. 6: a) HTC yield of materials made at 180°C at different T/S proportions and of CH50S50T samples prepared at 160 and 200°C; b) Corresponding BET areas A_{BET} after HTC and subsequent pyrolysis at 900°C. The dashed lines in a) were calculated (see text), and are just guides for the eye in b).

780 Fig. 7: BET areas A_{BET} (open symbols) and product Total carbon yield $\times A_{BET}$ (full symbols)
781 as a function of the total carbon yield for materials at different T/S proportions after HTC at
782 180°C and subsequent pyrolysis at 900°C.

783 Fig. 8: a) Nitrogen adsorption-desorption isotherms (full and open symbols, respectively) at -
784 196°C for CH50S50T180_2 and CH50S50T180_u samples; and b) their pore size
785 distributions determined by the DFT method (slit-like pore geometry).

786 Fig. 9: a) Van Krevelen diagram for all materials before (100S0T and 0S100T) and after HTC
787 (H100S0T and H0S100T) at 160, 180 and 200°C, at unmodified pH (HsStT_u) and at pH 2
788 (HsStT_2) and posterior pyrolysis at 900°C (HTC_900°C); and b) total amounts of CO and
789 CO₂ gases produced during TPD analysis for materials after HTC at 180°C at different weight
790 fractions of tannin.

791 Figure 10. Cyclic voltammetry (CV) results obtained in a three-electrode cell in 1 mol L⁻¹
792 H₂SO₄ electrolyte: (a) CV curves recorded at 0.5 mV s⁻¹ scan rate; (b) CV curves recorded at
793 10 mV s⁻¹ scan rate; (c) Specific capacitance of the samples at scan rates between 0.5 and 100
794 mV s⁻¹; (d) Capacitance retention at scan rates between 0.5 and 100 mV s⁻¹.

795 Figure 11. Cyclic voltammetry (CV) results obtained in a three-electrode cell in 1 mol L⁻¹
796 H₂SO₄ electrolyte: (a, c, e) CV curves recorded at 0.5 mV s⁻¹ scan rate for the first cycle,
797 showing the redox peaks on both anodic and cathodic branches; (b, d, f) Evolution of the
798 potential difference (ΔE) between the maxima of the anodic and cathodic peak 1 as a function
799 of the cycle number; CV curves were recorded at scan rates between 0.5 and 5 mV s⁻¹ for
800 C0S100T, and between 0.5 and 2 mV s⁻¹ for CH50S50T180_1 and CH50S50T180_u.

801 Figure 12. (a, c, e) Dependence of the anodic and cathodic peaks currents, $I_{p,ox}$ and $I_{p,red}$, on
802 the square root of the scan rate, $s^{1/2}$; (b, d, f) Evolution of the peak potentials, $E_{p,ox}$ and $E_{p,red}$,
803 versus the natural logarithm of the scan rate, $\ln s$.
