15 Abstract

A new phenomenological strain hardening function is proposed to describe the strain 16 17 hardening behavior of metallic materials. The function is based on a simplification of an earlier established self and latent hardening crystal plasticity approach. The proposed 18 function contains only four parameters, which can be readily obtained using an efficient 19 numerical technique by fitting the experimental curve. Several applications on different 20 21 materials are presented and good agreements with the experimental counterparts were obtained. One great advantage of the proposed empirical function is that its parameters can be 22 23 directly used in polycrystal viscoplastic modeling (VPSC approach) for crystal plasticitybased incremental strain hardening simulations. For the conversion of the parameters between 24 25 the macroscopic scale and the grain-level, the Taylor factor was used, which was re-defined for polycrystals in the present work. The VPSC simulations also led to good reproduction of 26 the experimental strain hardening behavior for all investigated cases, with rapid convergence. 27

31 1. Introduction

Strain hardening is considered to be one of the most important strengthening 32 mechanisms as it plays a critical role in evaluating the material's functional properties and 33 determines its suitability for engineering/structural applications. In general, such a 34 35 characteristic response is obtained experimentally from the macroscopic response of a specimen loaded under simple compression, tension, or shear in the form of a stress-strain 36 curve. Depending on material properties (such as crystal structure, grain size, etc.) and 37 imposed loading conditions, the shape of a stress-strain curve varies significantly and 38 frequently shows distinct stages [1-8]. In this aspect, finding a suitable empirical function that 39 can reproduce the experimental measurements is a challenging task and has been the subject 40 of numerous investigations. Indeed, analytical functions are useful in assessing material 41 42 performance for design purposes.

Under this premise, well-known and widely used classical constitutive relations either 43 follow a power-law or an exponential form. Examples for the former were suggested by 44 Ludwik [9], Hollomon [10], and Swift [11], while the Voce-approach [12] was proposed for 45 the latter. The drawback of the mentioned power-law form approaches is that there is no 46 upper limit for the flow stress, while a final saturation stage of strain hardening is frequently 47 observed, especially during severe plastic deformation [3]. To account for the saturation 48 stress, the exponential form of the Voce-equation [12] has received special attention in which 49 the flow stress approaches an asymptotic value at a high strain level. Subsequently, several 50 approaches were proposed in this context that used an increased number of fitting parameters 51 52 to capture the stress-strain response [1,13]. Chinh et al. [3] introduced an exponential powerlaw constitutive relationship that reduces to the conventional Hollomon power-law 53 relationship at low strains and to the Voce exponential relationship at high strains. They 54 demonstrated that the approach was effective in capturing the stress-strain relationship of 55 high purity aluminum and copper over a wide range of strain, however, non-negligible 56 deviations still existed in their findings for high strains. Recently, Lavakumar et al. [7] 57 presented an improved empirical version of the Ludwigson [1] equation with additional terms 58 and fitted parameters and applied successfully to several materials. Other approaches were 59 based on the physical deformation mechanisms observed at the dislocation scale, for 60 example, the Kocks-Mecking approach, which is very suitable for Stage III hardening [14-16] 61 and the dislocation cell-based theory of Estrin et al. [2] to reproduce Stages III and IV. 62

63 Besides, the fit of an experimental stress-strain curve is also possible by crystal plasticity-based approaches where the parameters refer to strain hardening of individual slip 64 systems, capable of distinguishing self and latent hardening [17-20] using a power-law 65 relation with a saturation stress. Such physically-based approaches have proven to be 66 effective for many materials and are well suited for a wide variety of loading conditions as 67 well as deformation to large strain regimes (for example: Zhou et al. [19]; Wu et al. [21]; 68 69 Dhinwal and Toth [22]; Sahoo et al [23]; Vu et al. [24]). Nevertheless, one of the challenges of such approaches is to determine the optimal values of the crystal plasticity-based strain 70 71 hardening parameters. In this regard, various experimental [25-27] and computational [28-31] optimization methodologies were suggested to identify an optimal set of material hardening 72 parameters for crystal plasticity models. The most conventional approach for identifying 73 74 crystal plasticity hardening parameters is to carry out simple mechanical tests on a single crystal [25,26]. However, this is seldom practiced as most of the materials are often available 75 76 as polycrystals, and the boundary conditions are very different for a crystal embedded into the polycrystal. A usual way is to use the inverse analysis technique which involves 77 calibrating the material parameters until the simulation results match the experimental data. 78 79 This is primarily based on the least-square method or simply using a trial-and-error approach. 80 The former refers to an optimization process where a set of parameters is recognized for an objective function that minimizes the variance between the experimental data and the 81 82 computed response. While the latter corresponds to a manual searching of each parameter by iteratively fitting the experimental curve. However, both of these approaches require initial 83 84 estimation of the parameter values and involve a large number of iterations in an effort to converge to an optimal solution. At the same time, such techniques reflect two key sources of 85 86 ambiguity for the quantitative estimation of parameters: (i) *uncertainty*, which occurs because 87 of the presence of numerous associated unknown parameters within the phenomenological 88 constitutive law, such that the effect of one parameter can be compensated by the other set of parameters on the course of strain hardening, and (ii) inconsistency, because the obtained 89 values of the parameters are arbitrary. Consequently, to validate the experimental findings, 90 these techniques are very complex and usually it is difficult to interpret the physical meaning 91 of the parameters. 92

93 Therefore, to exploit the full predictive potential of the adjustable hardening 94 parameters in a single expression, it is necessary to establish a meaningful and optimized set 95 of hardening parameter values. With the advancement in computational technology, several

96 researchers have proposed inverse analysis strategies for the computational optimization algorithm by employing sophisticated experimental techniques [32-39]. The experimental 97 results can be achieved by the most commonly available instrumented techniques such as 98 nano-indentation or digital image correlation (DIC). The former involves probing individual 99 100 grains within the polycrystal and extracting the indentation stress-strain response in the form 101 of the load-displacement curve for several grains within the polycrystal, which is then used to 102 construct the macroscopic response [32-37]. In this regard, Patel et al. [35] utilized spherical indentation to establish a correlation between the indentation stress-strain curve and the 103 104 uniaxial stress-strain curve via simple scaling factors. Subsequently, they validated these scaling factors using a finite element (FE) model. Mandal et al. [36] established a canonical 105 correlation analysis to explain the influence of the constitutive model parameters on the flow 106 107 stress behavior within the framework of the mechanical threshold stress (MTS) model [40]. However, owing to the complex stress state beneath the indenter, it is difficult to interpret the 108 experimental results and obtain the parameters that govern the hardening behavior. Also, 109 these experimental strategies are very time-consuming as the number of experiments to be 110 carried out on several grains is large, and incurs a huge experimental cost, with an additional 111 drawback of the indentation size-effect. 112

113 Alternatively, within the framework of experimental techniques, DIC enables the measurement of spatial displacement and strain fields and provides an insight into the 114 micromechanics of solids. Guery et al. [38] used the inverse analysis technique for coupling 115 the experimentally measured spatial strain fields produced via DIC and the weighted finite 116 element modeling update (FEMU) scheme for qualitative estimation of the crystal plasticity 117 parameters. The FEMU approach is based on comparing the results of FE modeling with 118 experimental results, by minimizing the error. However, to converge into an acceptable 119 120 solution, the method requires numerous FEM calculations. Despite these advancements, a time-efficient methodology is always sought which could overcome the computational cost 121 and at the same time provide an approximation to the values of the uncertain parameters 122 123 present in the strain hardening functions.

Based on this perspective, the present investigation is undertaken with two major objectives: (i) A new analytical version of the strain hardening function based on a power-law relation is proposed, which has its origins in crystal plasticity. Unlike all other existing empirical power-law functions, this power-law function is unique in the sense that it has saturation stress that can drive the flow stress to saturation. (ii) A suitable minimization 129 technique is proposed for determining the optimal values of the unknown hardening constants. The reliability of the proposed approach was tested critically by applying it to 130 different materials: Aluminum, Copper, Steel, and Titanium, undergoing various deformation 131 modes, such as tensile, compression, as well as torsion testing, and demonstrated good fitted 132 response. To this end, the parametric values obtained from the proposed procedure were also 133 employed in a crystal plasticity framework, which includes much more physics on the 134 deformation of the polycrystal than a phenomenological function. The VPSC (viscoplastic 135 self-consistent) polycrystal model was used for this purpose, and the obtained strain 136 hardening was also in good agreement with the experiments, like the phenomenological one. 137 The great advantage of doing first a phenomenological fitting before the VPSC simulation is 138 that the phenomenological parameters serve as an excellent initial guess for the crystal 139 plasticity simulations. In this way, the VPSC simulation work is highly reduced, and the 140 obtained results are remarkable. 141

142

143 2. The principles of the new strain hardening function

In crystal plasticity, strain hardening is frequently modeled using self and latent hardening of the slip systems. One of the frequently used approach was introduced by Kalidindi et al. [18], then later modified by Zhou et al. [19]. It expresses the influence of all slip systems on the hardening rate of a given slip system '*i*' and is given by:

148
$$\dot{\tau}_0^i = \sum_{j=1}^n q_c^{ij} h_c \left(1 - \frac{\tau_0^j}{\tau_{sat}^i} \right)^{a_c} \left| \dot{\gamma}^j \right|. \tag{1}$$

Here, τ_0^i is the resolved shear stress in slip system *i*, $\dot{\gamma}^j$ is the resolved shear strain rate in the slip system *j*, and *n* is the total number of slip systems. q_c^{jj} denotes a $(n \ge n)$ matrix and accounts for the self and latent interactions between the slip systems (the index 'c' stands for 'crystal plasticity'). The diagonal elements of q_c^{jj} represent the effect of self-hardening, while the off-diagonal parts are the latent hardening terms [17]. h_c and a_c are the hardening parameters, and τ_{sat}^i denotes the saturation stress. The essential novelty of the present work is to use an analytical version of this hardening rule, applicable at the macroscopic level:

156
$$\dot{\sigma}_{0}(\overline{\varepsilon}) = h \left(1 - \frac{\sigma_{0}(\overline{\varepsilon})}{\sigma_{sat}} \right)^{a} \overline{\dot{\varepsilon}} .$$
 (2)

Here $\overline{\dot{\varepsilon}}$ is the macroscopic von-Mises equivalent strain rate and σ_0 is the reference strength of the material, which appears in the strain rate sensitive power-law formula of viscoplastic behavior:

160
$$\sigma(\overline{\varepsilon}) = \sigma_0(\overline{\varepsilon}) \left(\frac{\overline{\dot{\varepsilon}}}{\overline{\dot{\varepsilon}}_0}\right)^m,$$
(3)

161 with *m* being the macroscopic strain rate sensitivity index and $\overline{\dot{\mathcal{E}}}_0$ the reference strain rate.

It should be noted here that in the above formulation, the self and latent hardening have been simplified and thus, do not appear in the formula. Also, while there can be several different values for τ_{sat}^{i} in Eq. (1), the macroscopic curve can contain only one parameter for the saturation stress; σ_{sat} . After separating the variables and integrating Eq. (2), the following form of the strain hardening function can be obtained:

167
$$\sigma_0(\overline{\varepsilon}) = \sigma_{sat} - \sigma_{sat} \left[\left(\frac{h(a-1)}{\sigma_{sat}} \right) \overline{\varepsilon} + \left(1 - \frac{\sigma_{00}}{\sigma_{sat}} \right)^{1-a} \right]^{\frac{1}{1-a}}, \text{ where } a \neq 1.$$
(4)

Here σ_{00} is the yield strength of the material (at $\overline{\epsilon} = 0$). The number of unknown parameters in this function is four; they are: σ_{00} , σ_{sat} , *h*, and *a*. Among these, σ_{00} can be readily assigned from the experiment. While the values of the remaining three parameters (i.e., σ_{sat} , *h*, and *a*) cannot be assigned directly; they need to be identified from the experimental curve using a suitable fitting procedure. A relatively simple and fast procedure is a minimization technique, which is presented in the next section.

174

175 **3.** Parameter identification procedure

176 The first parameter is the yield stress (σ_{00}), thus the flow stress value at the 177 beginning of the plastic strain ($\varepsilon = 0$). To obtain the other three parameters, a large number of 178 co-ordinate points were selected on the experimental flow stress curve; typically, about N=50, 179 and the following scalar function was defined:

180
$$f = \sum_{i=1}^{N} \left| \sigma_i^{sim}(\overline{\varepsilon}_i) - \sigma_i^{exp}(\overline{\varepsilon}_i) \right| = \min.$$
(5)

181 Here the superscripts 'sim' and 'exp' stand for the stress value from Eq. (4), and the experimental one, respectively. An efficient procedure for minimizing this function is to 182 employ a suitable bracketing technique until the function's value (f) approaches zero with the 183 specified precision. To begin the bracketing process, large initial intervals were defined for 184 each of the three parameters. In the current study, the intervals of the parameters were: $\sigma_{sat} \in$ 185 $[\sigma_{00}, 1000 \text{ MPa}], h \in [0, 100000 \text{ MPa}], \text{ and } a \in [1, 10, a \neq 1]$. At the very beginning, each of 186 187 these intervals were divided into 100 equal intervals and the function values f were calculated for all possible combinations of the 100^3 parameter values, then the parameter combination 188 corresponding to the minimum f value was identified. Subsequently, in the next iteration, the 189 same procedure was repeated on the reduced intervals (which were divided into 100 190 intervals), and the cycle continued several times, until the minimum f value reached the 191 required precision (0.01 MPa). The mentioned procedure is computationally very fast, it 192 converges in seconds to achieve the specified precision [see the Fortran program as an 193 additional available material at LaszloSToth/Hard-fit-by-minimization: An efficient Fortran 194 195 program to fit a stress-strain curve by the empirical function derived from crystal plasticity. 196 (github.com)].

197 For the special case, when a = 1, we obtain from Eq. (2):

198
$$\boldsymbol{\sigma}_{0}(\overline{\boldsymbol{\varepsilon}}) = \boldsymbol{\sigma}_{00} + h' \cdot \overline{\boldsymbol{\varepsilon}} , \text{ where } h' = h \cdot \left(1 - \frac{\boldsymbol{\sigma}_{00}}{\boldsymbol{\sigma}_{sat}}\right) . \tag{6}$$

199 So, for a = 1, the strain hardening is linear. Therefore, for linear hardening, the meaning of 200 the σ_{sat} parameter is not a saturation stress, it is just a parameter with stress dimension. In 201 this case, only one point is needed from the experimental curve to obtain the value of the h'202 parameter (if σ_{00} can be read from the experimental curve). The proposed new function in Eq. (2) can only describe hardening, because the term $\left(1 - \frac{\sigma_0(\overline{\varepsilon})}{\sigma_{sat}}\right) \text{ must be positive. Softening corresponds to } \sigma_{sat} \leq \sigma_0(\overline{\varepsilon}) \text{. In this case, the}$

205 integration of Eq. (2) leads to the following:

206
$$\sigma_0(\overline{\varepsilon}) = \sigma_{sat} + \sigma_{sat} \left[\left(\frac{h(a-1)}{\sigma_{sat}} \right) \overline{\varepsilon} + \left(\frac{\sigma_{00}}{\sigma_{sat}} - 1 \right)^{1-a} \right]^{\frac{1}{1-a}}, \quad \text{(for softening: } \sigma_{sat} \le \sigma_{00} \text{).} \quad (7)$$

207

4. Use of the macroscopic hardening parameters in polycrystal plasticity simulations

One of the main goals of the proposed methodology is to evaluate and assess the 210 identified hardening parameters so that they can be conveniently used in crystal plasticity 211 simulations. Indeed, it is a challenging task to perform a high-quality numerical work for 212 simulating the macroscopic strain-hardening behavior of polycrystals with crystal plasticity 213 approach. Nevertheless, it is often successful, as there are excellent simulation results 214 published in several studies [22-24, 41-45]. The usual technique used is trial and error, which 215 216 requires many iterations. However, when there are initial parameters that are already good approximations, the task becomes much more efficient. Indeed, as the proposed macroscopic 217 strain hardening function was obtained by simplifying a microscopic (crystal plasticity) 218 modeling function, it is possible to use the macroscopic parameters as a good initial guess for 219 the crystal plasticity simulations. 220

There are differences between the values of the macroscopic and microscopic 221 hardening parameters which are due to the difference in the scale of the mechanical behavior. 222 223 Therefore, one has to link the two scales. One possibility is to use the Taylor factor which relates stress and strain between the two scales. The Taylor factor is based on the energy 224 balance between the grains ('internal energy') and the macroscopic sample ('external 225 energy'). For linking the microscopic and macroscopic properties, the polycrystal has to be 226 considered as a composite material. Therefore, the Taylor factor has to be based on an energy 227 relation that is established for composites. In all previous works, the Taylor factors used for 228 polycrystals were based on the equality of the external and 'the apparent internal energies' 229 (see its definition in the Appendix), which is valid only in two cases: iso-stress and iso-strain, 230 or also called Static and Taylor approaches. In other approaches (like the widely used Self-231

Consistent model), the external and the 'apparent internal energies' are not equal, so a correction is needed. Moreover, there are actually two kinds of Taylor factors; one used for the strains (equivalent strain macroscopically and crystallographic resolved shear strain within the grains) and another which is relating the stresses between the two scales (equivalent stress at the macroscopic level, and crystallographic resolved shear stress in the grains). The definitions of the two kinds of Taylor factors were established in the Appendix in such a way that the energy balance for polycrystals is correctly used.

239 We recall first the resulting definition relating the strain quantities:

240
$$M(\text{for strain}) = \frac{\sum_{g=1}^{n_g} \sum_{f=1}^{n_s} \sum_{s=1}^{n_s} \left(\left| \dot{\gamma}_s^f \right| \cdot v_g \right)}{\overline{\dot{\mathcal{E}}_c}} , \qquad (8)$$

Here $\dot{\gamma}_s^f$ is the slip rate in the slip system identified with the index 's' for the slip-family 'f' (if there is more than one slip system family; frequent in b.c.c. and h.c.p. crystal structures), whereas, n_f is the number of slip families, and n_s is the number of slip system in a slip family. n_g is the number of grains and v_g is the relative volume fraction of the grain (so that the total volume is 1.0). The Taylor factor for converting the stress quantities at the two scales is:

247
$$M^{(\text{stress})} = \frac{\overline{\sigma}_c}{\lambda \cdot \overline{\tau}_r} , \qquad (9)$$

where $\overline{\sigma}_c$ is the macroscopic equivalent stress and $\overline{\tau}_r$ is the average resolved shear stress in the slip systems (see its definition in the Appendix). The λ parameter expresses the ratio of the 'external energy' to the total 'apparent internal energy' of the individual grains:

251
$$\lambda = \frac{\underline{\sigma}_{c} : \underline{\underline{\dot{E}}}_{c}}{\sum_{g=1}^{n_{g}} \underline{\overline{\sigma}}_{g} : \underline{\underline{\ddot{E}}}_{g} \cdot v_{g}} \quad .$$
(10)

Here $\underline{\sigma}_c$ and $\underline{\dot{E}}_c$ are the stress and strain rate tensor at the macroscopic level, $\underline{\sigma}_g$, $\underline{\dot{E}}_g$ are the same at grain level. (Note that λ is <u>not</u> equal to 1.0 in composite materials, see in Ref. [46].)

254 The Taylor factor for converting the strain quantities at the two scales is:

255
$$M^{(strain)} = \frac{\sum_{g=1}^{n_g} \sum_{f=1}^{n_f} \sum_{s=1}^{n_s} \left(\left| \dot{\gamma}_s^f \right| \cdot v_g \right)}{\overline{\dot{\varepsilon}}} \quad . \tag{11}$$

By doing so, the M factors for strains (Eq. 8) and for stresses (Eq. 9) are always equal. The reason for using one or the other depends on what physical quantity is required to be converted between the macroscopic and microscopic levels.

What is needed for the polycrystal simulation is to obtain the values of the microscopic hardening parameters appearing in Eq. (1) (τ_0 , h_c , a_c , τ_{sat}) from the macroscopic ones in Eq. (4) (σ_{00} , h, a and σ_{sat}). Using the Taylor factor defined in Eq. (9) for stresses, the transformation formulas are:

$$\tau_0 = \sigma_{00}/M, \tag{12}$$

$$\tau_{scat} = \sigma_{scat} / M, \tag{13}$$

266

264

$$h_c = h/M^2, \tag{14}$$

. . _.

$$a_{\rm c} = a \ . \tag{15}$$

First, we examine how to apply these formulas when there is only one slip system family that 267 268 contributes to the plastic deformation. The Taylor factor can be determined using the polycrystal plasticity code just by doing a single small strain increment, and applying Eq. (9). 269 In such a calculation, the value of T_0 can be arbitrary because M is the ratio of the 270 macroscopic flow stress and the resolved shear stress, while the macroscopic stress is 271 proportional to the resolved shear stress. Having the Taylor factor, all microscopic strain 272 hardening parameters can be obtained by employing Eqs. (12-14), and a full simulation can 273 be done. Nevertheless, before starting a full simulation, it is useful to verify that the 274 macroscopic yield stress is reproduced by the employed Taylor factor. Thus, a single step 275 simulation is required to verify that σ_{00} is actually reproduced by the VPSC simulation. This 276 is not guaranteed because a uniform au_0 value is used for each grain, while in the real 277 material, the physical quantities are never so ideally homogeneous as in the simulations. 278 279 Besides, there can be also differences in the grain shapes, or initial texture, both leading to deviations in the Taylor factor of the real material and the simulated one. For all these 280

possible reasons, an adjustment of the Taylor factor might be needed to assure that Eq. (12) 281 becomes valid. This adjustment is simply a multiplication of the simulated Taylor factor by 282 the ratio of the second and the first simulated yield stresses. Once this step is achieved, M and 283 au_0 are known, and one can determine the other three microscopic parameters using Eqs. (13-284 15). After this, a full simulation can be performed by the polycrystal code to obtain the 285 macroscopic stress response of the polycrystal. If needed, minor adjustments of the parameter 286 values can still be done to reproduce the experimental measurements better. In the 287 applications presented in this work, only the value of τ_{sat} was needed to be slightly changed 288 to fit the curves well at higher strains. Concerning the self and latent hardening parameters (289 q_c^{ij}), earlier simulation works have led to general constant values by grouping them into four 290 categories [19], according to the geometrical relation between the slip systems: $q_c^{(1)}=1$ for 291 coplanar slip, $q_c^{(2)} = 1.2$ for collinear slip, $q_c^{(3)} = 1.4$ for perpendicular slip, and $q_c^{(4)} = 1.2$ for all 292 other geometrical situations. These values were used for all simulation cases. 293

On the other hand, assigning the microscopic hardening parameters is a more 294 complex task when several slip system families are active in the material. In this case, the 295 296 following strategy was adopted in the present work. For the n_f number of families, there are n_f number of τ_0^i and τ_{sat}^i values ($i = 1..., n_f$). Previous simulation works have led to a set of 297 \mathcal{T}_0^i values, so in the first attempt, they were adopted for calculating the yield stress of the 298 material. In case of difference between the simulated and experimental macroscopic yield 299 stress, the τ_0^i values were scaled proportionally so that the yield stress were the same. This 300 301 procedure permitted also to obtain a Taylor factor which was then used for calculating the other parameters. Concerning τ_{sat}^{i} , a single value was assigned for each slip system family, 302 according to Eq. (13). 303

The VPSC polycrystal code in its version developed by Molinari and Toth [47] was employed to predict the Taylor factor (M) as well as to simulate the mechanical response of the polycrystal in the form of stress-strain curves. To constitute the polycrystal, 6000 grain orientations were selected from the measured texture (when it was available), or a random texture was used if the initial texture was not known. For this purpose, the ATEX software [48] was used for the discretization procedure. The strain rate sensitivity index (m) of slip was taken as 0.05 and the α coefficient in the localization law of the self-consistent model was 0.7 (see Molinari and Toth [47] for the details of the VPSC approach used). The flow stress was obtained from the macroscopic stress and strain rate tensors as a work conjugate quantity to the von-Mises equivalent strain rate $\dot{\bar{\mathcal{E}}}_c$:

314
$$\overline{\sigma}_{c} = \left(\underline{\sigma}_{c} : \underline{\dot{e}}_{c}\right) / \overline{\dot{e}}_{c}.$$
(16)

315 (Note that here $\overline{\sigma}_c$ is not a von-Mises equivalent stress as the polycrystal is not an isotropic 316 von-Mises material.) Subsequently, the stress-strain curves were plotted using $\overline{\sigma}_c$ as a 317 function of $\overline{\mathcal{E}}_c$.

318

319 **5. Results**

The new analytical strain hardening function presented in Eq. (4) was tested for 320 different deformation modes and for materials exhibiting different forms of crystal structures, 321 such as face-centered cubic (FCC), body-centered cubic (BCC) and hexagonal closed packed 322 323 (HCP). The considered deformation modes were uniaxial tension, compression and torsion testing. The experimental results for evaluating the mechanical response of the materials were 324 adopted from published literature on aluminum [24,49], commercially pure (CP) copper 325 (C110) [50], low carbon steel [22] and titanium (CP-grade 2) [51]. This includes deformation 326 ranging from intermediate to high strain levels. The experimental curves were reproduced in 327 Fig. 1a for aluminum (Al 2024 in T351 state) subjected to uniaxial tension, compression and 328 torsion [49], in Fig. 1b for uniaxial tensile test of copper (C110) [50] as well as for low 329 carbon steel [22]. Fig. 1c presents the stress-strain curve for high torsion strain level for 330 aluminum (Al 1050) [24] and for copper (C110) [50]. Fig. 1d displays the case of HCP-Ti 331 (CP-grade 2) alloys under uniaxial tensile tests at room temperature (RT) and at 300°C [51]. 332

For all these above-mentioned cases, the macroscopic parameters were first determined using the presented minimization technique and a comparison of the fitting curves with the experimental ones was accomplished, as discussed in Sec. 5.1. Subsequently, the macroscopic parameters obtained from the analytical approach were transformed into the microscopic ones, i.e., to the grain level, and then simulations were performed using the
VPSC code to predict the strain hardening responses, see Sec. 5.2.

339 5.1. Results obtained from fitting the mechanical response by the phenomenological 340 hardening function

Fig. 1 presents the fitted stress-strain responses obtained using the analytical 341 342 hardening function (Eq. 4) in comparison with the experimental counterparts for the different sets of materials mentioned above under different loading conditions, i.e., tension, 343 compression and torsion. It can be seen that the analytical hardening function (identified as 344 'fitted' in Fig. 1), precisely captures the experimental stress-strain curves. One can appreciate 345 346 the quality of the fitted stress-strain plots by the analytical hardening function by the fact that we are using only four parameters (i.e., σ_{00} , σ_{sat} , h and a), to reproduce the entire plastic 347 part of the strain hardening curve. Table 1 summarizes the fitted hardening parameters for 348 each of the curves presented in Fig. 1. 349

350 5.2. Predicting strain hardening using the VPSC crystal plasticity approach

351 Figs. 2-5 present the predicted mechanical response and the corresponding strain hardening rate plots obtained by VPSC simulations in comparison with experiments. Results 352 are shown first for the lower strain regime for different strain paths in Fig. 2 for aluminum, 353 and in Fig. 3 for copper and steel. The results for large strain hardening in torsion are 354 355 presented in Fig. 4 for copper and aluminum. A representative example is also shown for hexagonal crystal structure; for Titanium, see Fig. 5, for two cases: tension parallel (Fig. 5b-356 357 c) and perpendicular (Fig. 5d-e) to the rolling direction of the sheet from which the tensile sample was cut. Whenever the experimental initial texture was available (as indicated in 358 Table 2), it was used in the form of a polycrystal with 6000 grains for the VPSC polycrystal 359 360 simulations; they are also shown in the figures in form of pole figures. When the initial texture was unknown, a random texture was used, also with 6000 grains. One can see that the 361 VPSC simulations reproduce perfectly the experimental curves, just like 362 the phenomenological fitting as shown in Fig. 1. 363

As there is very good agreement between the VPSC-simulated and experimental strain hardening curves, the agreement is also good for their derivatives; $\theta = d \overline{\sigma}/d\overline{\varepsilon}$, which constitutes the so-called Kocks-Mecking plot as a function of stress, see in Figs. 2-5. The well-known Stage III and IV hardening stages are indicated for the case of copper andaluminum in Fig. 4.

369

370 **6.** Discussion

As the present work has two major parts, we first discuss about the new phenomenological function, and then the crystal plasticity simulations will be examined. Finally, the discussion part will be closed with an evaluation of the applicability conditions for both of these approaches.

375 6.1. Discussion on the new phenomenological strain hardening function

The new strain hardening function has four parameters, which is a relatively low number with respect to other propositions (for example, the recent modified Ludwigson function [7] has six parameters). In order to obtain the values of the parameters, we established a rapid minimization procedure using about 50 representative points from the experimental curve (Section 3).

It is also important to compare the performance of the new proposed 381 phenomenological hardening function to that of existing ones. In this regard, we have carried 382 out such comparisons with two previous propositions: with Chinh et al. [3], and with 383 Lavakumar et al. [7]. Chinh et al. [3] presented a mixed exponential power-law empirical 384 relation for reproducing especially the asymptotic limiting stage (see their equation in Fig. 385 6a). The fitted hardening curves in Fig. 6b correspond to the same experimental curves but 386 obtained by the present phenomenological approach. As can be seen, the agreement is better 387 388 with the present approach, while both approaches use the same number of parameters (four).

Lavakumar et al. [7] proposed a modification to the Ludwigson [1] equation which is a mixed power-law and exponential function (see the function in Fig. 7a). They reproduced satisfactorily the strain hardening behavior of various metallic materials when deformed to a low strain regime (Fig. 7a). We applied our function as well on the same data basis; see the results in Fig. 7b. Closer inspection reveals that our function approaches the experimental curves in better accordance by using only four parameters as compared to six in the modified Ludwigson function.

396 6.2. Discussion on the crystal plasticity simulations

397 Tables 3-6 lists the parameters used for predicting the mechanical response using the VPSC approach. They were obtained from the phenomenological analysis by transforming 398 the parameters to the grain level with the help of the Taylor factor. The adjusted Taylor 399 factors are presented in Table 2 together with the simulated Taylor factors (the latter in 400 parenthesis). The difference between the Taylor factors was pointed out in Section 4 above; 401 possibly due to the non-uniform initial strengths of the slip systems in the material, the 402 403 crystallographic texture (if was not known, so a random texture was used), or the differences in the assumed and experimental grain shapes. Table 2 presents also the values of the λ 404 parameter, which expresses the ratio of the external plastic power to the 'apparent internal' 405 one (which is the sum of the individual grain-powers). This issue was also examined in the 406 recent work of Sahoo et al. [46] where the strain hardening behavior of two-phase composites 407 408 were modeled using a plastic power-based composite approach. The range of λ found in the 409 present work is between 1.06 and 1.16, which is quite similar to the range found in Sahoo et al. [46]. λ is always larger than 1.0, meaning that the 'apparent internal plastic power' 410 calculated within the grains is less than the macroscopic plastic power. As discussed in Sahoo 411 412 et al. [46], the origin of this unbalance of plastic powers can be attributed to the non-uniform distribution of the stress and strain within the components of the composite, that is, within the 413 414 grain-interiors of the polycrystal.

415 **6.3.** Model limitations

The present modeling is presented for two levels: at the macroscopic level, where the 416 hardening function is totally empirical, and at grain level, for crystal plasticity simulations. 417 418 The limitations of these two modeling have to be discussed for both the conditions. For the phenomenological case, the function can describe continuous hardening (also continuous 419 420 softening). As no information is used on the metallurgical state of the metal in the parameter fitting, the parameters are not directly related to a specific material state. Nevertheless, as the 421 422 proposed function is able to capture the strain hardening response of the material up to large 423 strains (see the torsion example) where significant microstructural evolution is taking place, 424 somehow the parameters are related to those changes. They are: evolution in dislocation density, changes in dislocation cell-size (for alloys showing dislocation cell structures), 425 426 variation in grain size due to grain fragmentation, or texture evolution due to deformation.

427 On the contrary, for the crystal plasticity modeling, only crystallographic glide was 428 used as a possible deformation mechanism, so the application is more limited. For that case, it is implicitly assumed that the metallurgical state of the alloy does not change during
deformation due to phase transformations, twinning or recrystallization. It is designed
actually for isothermal conditions and constant strain rate, and not applicable when twinning,
phase transformation or dynamic recrystallization is taking place during plastic deformation.

433

434 **7.** Summary

The subject of this work is to propose a new strain hardening function with a small 435 number of parameters for use in engineering applications. The new function is based on an 436 earlier crystal plasticity-based hardening function proposed to describe the self and latent 437 hardening of single crystals. It has been successfully applied to several polycrystalline metals 438 with different crystallographic structures and compared with previous approaches. The 439 proposed hardening function has the significant advantage of containing parameters that can 440 be transformed into crystal plasticity parameters, thereby permitting them to be used directly 441 in polycrystal plasticity simulations. This conversion is based on the Taylor factor of the 442 polycrystal. Using these parameters in the VPSC polycrystal model, one can obtain an 443 accurate simulation of the strain hardening curve, like the one obtained by the 444 445 phenomenological crystal plasticity-based analytical hardening function. It was also shown in this work that there are two kinds of Taylor factors; one for converting the strain and another 446 447 for the stress quantities between the macroscopic and the grain levels. While they have the same values, their formulas are different; the stress-Taylor factor contains a parameter (λ) 448 which is related to the energy balance between the external and 'apparent internal plastic 449 450 power'. This parameter, however, can be readily obtained from the stress and strain quantities computed during the crystal plasticity simulation, and thus the conversion for the stresses is 451 straightforward. 452

460

Appendix

Taylor factor

461 The Taylor factor is employed to bridge the differences between two scales: the macroscopic462 one and the grain level. It can also be used for linking either the strains or stresses. The grain

is a crystal which deforms by slip on several slip systems simultaneously. First, we define the

464 Taylor factor for a single grain, and then for a polycrystal.

465 *<u>Taylor factor for single crystals</u>*

The slip systems are grouped into families in a grain, according to their common features. We denote the number of families by n_f and the number of slip systems within one family by n_s (the *f* index stands for 'family', and the *s* for slip). The basis for establishing the Taylor factor is the equality of the 'internal' and 'external' plastic power in unit volume:

470
$$\sum_{f=1}^{n_f} \sum_{s=1}^{n_s} \tau_s^f \dot{\gamma}_s^f = \sigma_{kl} \dot{\varepsilon}_{kl} \quad . \tag{A1}$$

Here τ_s^f is the resolved shear stress on a slip system, σ_{kl} is the stress tensor and $\dot{\mathcal{E}}_{kl}$ is the strain rate tensor. The latter tensorial quantities can be changed into scalars, where $\overline{\dot{\mathcal{E}}}$ is the von-Mises equivalent strain rate, and $\overline{\sigma}$ is the equivalent stress:

474
$$\sum_{f=1}^{n_f} \sum_{s=1}^{n_s} \tau_s^f \dot{\gamma}_s^f = \overline{\sigma} \cdot \overline{\dot{\varepsilon}} \quad . \tag{A2}$$

475 Note that $\overline{\sigma}$ is not the von-Mises equivalent stress (because a crystal is not an isotropic 476 material); it is the work-conjugate equivalent stress.

477 Using the slip rates, first we define the *average resolved shear stress* $\overline{\tau_r}$:

478
$$\overline{\tau}_{r} = \sum_{f=1}^{n_{f}} \sum_{s=1}^{n_{s}} \tau_{s}^{f} \dot{\gamma}_{s}^{f} / \sum_{f=1}^{n_{f}} \sum_{s=1}^{n_{s}} \left| \dot{\gamma}_{s}^{f} \right| \quad . \tag{A3}$$

479 Eq. (A2) now becomes:

480
$$\overline{\tau}_r \cdot \sum_{f=1}^{n_f} \sum_{s=1}^{n_s} \left\| \dot{\gamma}_s^f \right\| = \overline{\sigma} \cdot \overline{\dot{\varepsilon}} \quad . \tag{A4}$$

481 Using this equation, the Taylor factor M_g for a grain 'g' can now be defined in two forms, 482 one for the strains, and another for the stresses:

483
$$M_g^{(strain)} = \frac{\sum_{f=1}^{n_f} \sum_{s=1}^{n_s} \left\| \dot{\gamma}_s^f \right\|}{\dot{\bar{c}}}, \quad M_g^{(stress)} = \frac{\overline{\sigma}}{\overline{\tau}_r}.$$
 (A5a,b)

Note that these two kinds of Taylor factors have the same values. In crystal plasticity simulations, the Taylor factor can be readily calculated when all quantities needed for its definition are available. Note that in the work of Mecking et al. [52], Taylor factors were defined for single crystals, similarly to the present work, designed for strain and stress (Eqs. 5a,b); however, they were defined independently, resulting in disparities in values and making inconsistencies when they were employed.

490 <u>Taylor factor for polycrystals</u>

For polycrystals, the material has to be considered as a composite, made of single 491 492 crystals of the same material with number of components equal to the number of grains. The grains are anisotropic, so the difference between adjacent grains is coming from their 493 494 anisotropic mechanical behavior. For a composite material, the equality of the internal and external powers can only be used as volume integrals (Hill's lemma), contrary to the case of a 495 single-phase material (i.e., the single crystal), where the plastic power can be calculated by 496 the average values of stress and strain rate. First, we write the energy integral for the 497 498 polycrystal in the following two forms:

499
$$\sum_{g=1}^{n_g} \int_{V_g} \underline{\underline{\sigma}}_g(\underline{r}) : \underline{\underline{\dot{e}}}_g(\underline{r}) \cdot dV_g = \int_{V} \underline{\underline{\sigma}}(\underline{r}) : \underline{\underline{\dot{e}}}(\underline{r}) \cdot dV \quad . \tag{A6}$$

Here, $\underline{\underline{\sigma}}_{g}(\underline{r})$ and $\underline{\underline{\dot{E}}}_{g}(\underline{r})$ are the position dependent stress tensor and strain rate tensors in a grain 'g', while $\underline{\underline{\sigma}}(\underline{r})$, $\underline{\underline{\dot{E}}}(\underline{r})$ are actually the same, without distinguishing the grains. V_{g} is the volume of a grain, and V is the total volume of the polycrystal. According to Hill's lemma, the volume integral on the right side of Eq. (A6) can be replaced with the multiplication of the volume averages of the stress and strain rate tensors ($\underline{\underline{\sigma}}_c, \underline{\underline{\dot{E}}}_c$):

505
$$\int_{V} \underline{\underline{\sigma}}(\underline{r}) : \underline{\underline{\dot{\varepsilon}}}(\underline{r}) \cdot dV = \left(\int_{V} \underline{\underline{\sigma}}(\underline{r}) \cdot dV \right) : \left(\int_{V} \underline{\underline{\dot{\varepsilon}}}(\underline{r}) \cdot dV \right) .$$
(A7)

506 These volume integrals can be done grain by grain, so one can write:

507
$$\int_{V} \underline{\underline{\sigma}}(\underline{r}) \cdot dV = \sum_{g=1}^{n_g} \int_{V_g} \underline{\underline{\sigma}}_g(\underline{r}) \cdot dV_g = \sum_{g=1}^{n_g} \underline{\overline{\sigma}}_g \cdot V_g = V \cdot \underline{\underline{\sigma}}_c , \qquad (A8)$$

508
$$\int_{V} \underline{\underline{\dot{\varepsilon}}}(\underline{r}) \cdot dV = \sum_{g=1}^{n_g} \int_{V_g} \underline{\underline{\dot{\varepsilon}}}_g(\underline{r}) \cdot dV_g = \sum_{g=1}^{n_g} \overline{\underline{\dot{\varepsilon}}}_g \cdot V_g = V \cdot \underline{\underline{\dot{\varepsilon}}}_c , \qquad (A9)$$

where $\underline{\overline{\sigma}}_{g}$, $\underline{\underline{\vec{E}}}_{g}$ are the average stress and strain rate tensors within a grain indexed by g; $\underline{\underline{\sigma}}_{c}$, $\underline{\underline{\vec{E}}}_{c}$ are the macroscopic stress and strain tensors, respectively and n_{g} is the number of grains in the polycrystal. The right-hand side of Eq. (A6) can be called the macroscopic plastic power (P_{c}), so the energy balance expressed in Eq. (A6) can be rewritten as:

513
$$\sum_{g=1}^{n_g} \int_{V_g} \underline{\underline{\sigma}}_g(\underline{r}) : \underline{\underline{\dot{E}}}_g(\underline{r}) \cdot dV_g = V \cdot \underline{\underline{\sigma}}_c : \underline{\underline{\dot{E}}}_c = P_c \quad . \tag{A10}$$

514 On the other hand, Hill's lemma does not apply to the individual grains within the polycrystal 515 as a composite, so there is an inequality when one writes the following:

516
$$\sum_{g=1}^{n_g} \int_{V_g} \underline{\underline{\sigma}}_g(\underline{r}) : \underline{\underline{\dot{e}}}_g(\underline{r}) \cdot dV_g \neq \sum_{g=1}^{n_g} \left(\int_{V_g} \underline{\underline{\sigma}}(\underline{r}) \cdot dV_g \right) : \left(\int_{V_g} \underline{\underline{\dot{e}}}(\underline{r}) \cdot dV_g \right) = \hat{P} \quad .$$
(A11)

517 The right-hand side of this equation will be called hereafter the 'apparent internal plastic 518 power'; \hat{P} . The two integrals in Eq. (A11) are the average stress and strain values of the 519 stresses and strain rates within individual grains of the polycrystal, so \hat{P} can be written as:

520
$$\hat{P} = \sum_{g=1}^{n_g} \overline{\underline{\underline{\sigma}}}_g : \underline{\underline{\underline{E}}}_g \cdot V_g \quad . \tag{A12}$$

521 In a polycrystal plasticity modeling, both P_c and \hat{P} can be calculated, so by introducing a 522 scalar parameter (λ) between them, we can write:

523
$$\lambda \hat{P} = P_c$$
 (A13)

524 The value of λ is a measure of the deviation between the 'external plastic power' and the 525 'apparent internal plastic power':

526
$$\lambda = \frac{\underline{\underline{\sigma}}_{c} : \underline{\underline{\varepsilon}}_{c}}{\sum_{g=1}^{n_{g}} \underline{\overline{\sigma}}_{g} : \underline{\underline{\overline{\varepsilon}}}_{g} \cdot v_{g}}$$
(A14)

527 Here v_g is the volume fraction of a grain: $v_g = V_g/V$. As λ is defined by Eq. (A14), and all 528 quantities are available to calculate its value from a polycrystal plasticity code, the value of λ 529 can be calculated by Eq. (A14).

Now the apparent plastic power \hat{P} , defined by (A12), is rewritten for the polycrystal using the resolved shear stresses and resolved shear strain rates:

532
$$\hat{P} = V \cdot \sum_{g}^{n_g} \sum_{f=1}^{n_f} \sum_{s=1}^{n_s} \left(\tau_s^f \cdot \dot{\gamma}_s^f \cdot v_g \right) .$$
(A15)

This is done in order to replace the tensorial quantities with scalar ones. Similar change can be done also for the external plastic power, P_c . Using its expression given by the right-hand side of Eq. (A10), we write:

536
$$P_c = V \cdot \underline{\underline{\sigma}}_c : \underline{\underline{\dot{\varepsilon}}}_c = V \cdot \overline{\underline{\sigma}}_c \cdot \underline{\dot{\varepsilon}}_c \quad , \tag{A16}$$

where $\overline{\dot{\mathcal{E}}}_c$ is the von-Mises equivalent strain rate, and $\overline{\sigma}_c$ is the work-conjugate equivalent stress, defined by Eq. (A16):

539
$$\overline{\sigma}_{c} = \frac{\underline{\sigma}_{c} : \underline{\underline{\varepsilon}}_{c}}{\overline{\underline{\varepsilon}}_{c}} \quad , \tag{A17}$$

540 Then Eq. (A13) can be written as:

541
$$\lambda \cdot \sum_{g}^{n_{g}} \sum_{f=1}^{n_{f}} \sum_{s=1}^{n_{s}} \left(\tau_{s}^{f} \cdot \dot{\gamma}_{s}^{f} \cdot v_{g} \right) = \overline{\sigma}_{c} \cdot \overline{\dot{\varepsilon}}_{c} \quad .$$
(A18)

542 Similar to the case of single crystal, the expression of the average resolved shear stress $\overline{\tau}_r$ for 543 a polycrystal becomes:

544
$$\overline{\tau}_{r} = \sum_{g=1}^{n_{g}} \sum_{f=1}^{n_{f}} \sum_{s=1}^{n_{s}} \left(\tau_{s}^{f} \cdot \dot{\gamma}_{s}^{f} \cdot v_{g} \right) / \sum_{g=1}^{n_{g}} \sum_{f=1}^{n_{f}} \sum_{s=1}^{n_{s}} \left(\left| \dot{\gamma}_{s}^{f} \right| \cdot v_{g} \right)$$
(A19)

545 Eq. (A18) is written then:

546
$$\lambda \cdot \overline{\tau}_r \cdot \sum_{g=1}^{n_g} \sum_{f=1}^{n_f} \sum_{s=1}^{n_s} \left(\left| \dot{\gamma}_s^f \right| \cdot v_g \right) = \overline{\sigma}_c \cdot \overline{\dot{\varepsilon}}_c \quad . \tag{A20}$$

547 From this, the Taylor factor *M* for polycrystals is calculated in its two forms as:

548
$$M^{(strain)} = \frac{\sum_{g=1}^{n_g} \sum_{f=1}^{n_f} \sum_{s=1}^{n_s} \left(\left| \dot{\gamma}_s^f \right| \cdot v_g \right)}{\overline{\dot{\varepsilon}}} , \quad M^{(stress)} = \frac{\overline{\sigma}}{\lambda \cdot \overline{\tau}_r}, \quad (A21a,b)$$

where λ is computed from Eq. (A14). Note that the values of these two Taylor factors are the same. These definitions can be used in any polycrystal model as there was no implied assumption in its definition on the uniformity of strain (Taylor model), or the stress (Static model), or heterogeneous deformation (Self-consistent model, where both stress and strain in a grain can be different from the macroscopic ones).

Fig. 1. Fitted stress-strain response obtained from analytical phenomenological hardening curve, compared to measurements.

Fig. 2. VPSC simulation results for aluminum (Al 2024) in comparison with experimental measurements for (a) stress-strain response and (b) strain hardening rate.

Fig. 3. Initial input texture used for VPSC simulation for (a) Steel and (b) Copper (C110). Comparative plots of both the experimental and predicted (c) stress-strain response and (d) strain hardening rate behavior of both the tested specimens obtained from the VPSC simulation.

Fig. 4. Initial input texture used for VPSC simulation for (a) Aluminum (Al 1050) and (b) Copper (C110). Comparative plots of both the experimental and predicted (c) stress-strain response and (d-e) strain hardening rate behavior of both the tested specimens obtained from the VPSC simulation.

Fig. 5. Initial input texture used for VPSC simulation for (a) rolled titanium (CP-grade 2) sample similar to the published literature (Orozco-Caballero et al., 2018).
(b-e) Comparative plots of both the experimental and predicted stress-strain response and strain hardening rate behavior obtained from the VPSC simulation for tension parallel and perpendicular to the rolling direction at room temperature and 300°C.

Fig. 6. Comparison of the strain hardening plots between (a) the function of Chinh et al. (2004) and (b) the proposed analytical phenomenological function.

Fig. 7. Comparison of the strain hardening plots between (a) the modified Ludwigson function (Lavakumar et al. (2021)), and (b) the proposed analytical phenomenological function.

Figure	Material, Testing	Yield strength (σ_{00}) [MPa]	Saturation stress (<i>σ</i> sat) [MPa]	Hardening coefficient (h) [MPa]	Hardening exponent (<mark>a</mark>)
	Aluminium Compression at RT	355	995	30940	4.90
